1980 SELECTION OF MATERIALS FOR ROLLED-FILL EARTH DAMS
By **Charles H. Lee** 1
Discussion:
By T. T. Knappen 19
Paul Baumann 20
William C. Hill 25
A. Floris 26
Fred D. Pyle 27
Joel B. Cox 28
Stanley M. Dore 30
John E. Field 34
William P. Creager 37
Joseph Jacobs 39
C. H. Kadie, Jr. 47
Ralph Bennett 49
R. R. Proctor 50
L. F. Harza 52
Charles H. Lee 53

1981 INTERACTION BETWEEN RIB AND SUPERSTRUCTURE IN CONCRETE ARCH BRIDGES.
By **Nathan M. Newmark** 62
Discussion:
By A. Floris 81
Frank M. Baron 81
A. A. Eremin 83
Hardy Cross 86
Nathan M. Newmark 87

1982 ECONOMIC DIAMETER OF STEEL PENSTOCKS.
By **Charles Voetsch and M. H. Fresen** 89
Discussion:
By R. A. Monroe 106
William E. Rudolph 107
Peter Bier 108
Adolpho Santos, Jr. 110
Joseph D. Lewin 113
F. Knapp 121
Ralph W. Powell 123
H. K. Barrows 125
Robert W. Angus 126
M. H. Fresen 127

1983 STRESSES AROUND CIRCULAR HOLES IN DAMS AND BUTTRESSES.
By **I. K. Silverman** 133
Discussion:
By R. D. Mindlin 149
Chesley J. Posey 152
J. H. A. Brahtz 153
V. L. Fedorov 158
F. W. Hanna 163
C. P. Vetter 170
Fred L. Plummer 172
I. K. Silverman 177

No. PAGE

1984 RECLAMATION AS AN AID TO INDUSTRIAL AND AGRICULTURAL BALANCE.
By **Ernest P. Goodrich and Calvin V. Davis** 181
Discussion:
By JOSEPH JACOBS 213
M. E. McIVER 214
C. S. JARVIS 215
JOHN P. FERRIS 218
L. C. GRAY 220
CHARLES P. WILLIAMS 222
ERNEST P. GOODRICH AND CALVIN V. DAVIS 225

1985 CONSTRUCTION AND TESTING OF HYDRAULIC MODELS, MUSKINGUM WATER-SHED PROJECT.
By **George E. Barnes and J. G. Jobes** 227
Discussion:
By G. W. HOWARD 245
F. W. EDWARDS 245
T. T. KNAPPEN 247
RALPH W. POWELL 252
GEORGE E. BARNES AND J. G. JOBES 253

1986 ANALYSIS OF STRESSES IN SUBAQUEOUS TUNNEL TUBES.
By **A. A. Eremin** 256
Discussion:
By DAVID J. PEERY 266
ORRIN L. BRODIE 267
A. A. EREMIN 271

1987 DEFLECTIONS BY GEOMETRY.
By **David B. Hall** 275
Discussion:
By A. J. McGAW 288
L. E. GRINTER 290
RALPH W. STEWART 292
WILLIAM BERTWELL 297
DAVID B. HALL 300

1988 GRAPHICAL DISTRIBUTION OF VERTICAL PRESSURE BENEATH FOUNDATIONS.
By **Donald M. Burmister** 303
Discussion:
By WILLIAM P. KIMBALL 314
I. M. NELIDOV 315
GEORGE PAASWELL 318
JACOB FELD 320
NATHAN M. NEWMARK 321
A. E. CUMMINGS 324
D. P. KRYNINE 332
A. A. EREMIN 336
DONALD M. BURMISTER 337

1989 RAINFALL INTENSITIES AND FREQUENCIES.
By **A. J. Schafmayer and B. E. Grant** 344
Discussion:
By VICTOR H. COCHRANE 369
LEROY K. SHERMAN 370
J. O. JONES 372
CHARLES W. SHERMAN 380
GLEN N. COX 382
GARRETT B. DRUMMOND 383

No. PAGE

Eugene L. Grant.......... 384

C. S. Jarvis........................ 770
R. E. Redden........................ 771
Raymond A. Hill........................ 775
Nathan C. Grover and Charles Howard........................ 782

1995 PRACTICAL USE OF HORIZONTAL GEODETIC CONTROL.
By R. C. Sheldon........................ 791

Discussion:
By Philip Kissam........................ 803
Ralph Z. Kirkpatrick........................ 805

No. Page

E. B. Roberts 806
H. W. Hemple 808
J. C. Carpenter 812
George D. Whitmore 815
R. M. Wilson 816
Julius L. Speert 819
R. C. Sheldon 820

1996 PRESSURES BENEATH A SPREAD FOUNDATION.
By **D. P. Krynine** 827

Discussion:
By O. K. Fröhlich 850
Donald W. Taylor 852
Jacob Feld 853
G. P. Tschebotareff 854
A. Hrennikoff 859
Robert G. Hennes 865
T. A. Middlebrooks 868
A. A. Eremin 869
M. M. Buisson 869
Frederick J. Converse 874
D. P. Krynine 877

1997 EARTHQUAKE RESISTANCE OF ELEVATED WATER-TANKS.
By **Arthur C. Ruge** 889

Discussion:
By N. H. Heck 939
Mason A. Stone 940
H. C. Boardman 943
Franklin P. Ulrich and Dean S. Carder 945
Arthur C. Ruge 948

1998 BACK-WATER AND DROP-DOWN CURVES FOR UNIFORM CHANNELS.
By **Nagaho Mononobe** 950

Discussion:
By J. C. Stevens 990
Chesley J. Posey 992
A. A. Kalinske 993
Boris A. Bakhmeteff 997
P. Charles Stein 999
Nagaho Mononobe 1001

1999 READJUSTMENT OF TRIANGULATION DATUM.
By **Julius L. Speert** 1002

2000 STRUCTURAL ANALYSIS BASED UPON PRINCIPLES PERTAINING TO UNLOADED MODELS.
By **Otto Gottschalk** 1019

Discussion:
By L. J. Mensch 1043
Frederick Shapiro 1047
James R. Griffith 1049
Camillo Weiss 1050
F. B. Farquharson 1055
A. A. Eremin 1056
David M. MacAlpine 1057
Otto Gottschalk 1060

No. PAGE
2001 HYDRAULIC TESTS ON THE SPILLWAY OF THE MADDEN DAM.
By **Richard R. Randolph, Jr.** 1080

Discussion:
By Ettore Scimemi 1113
J. C. Stevens 1117
F. W. Edwards 1120
Morrough P. O'Brien 1122
Richard R. Randolph, Jr. 1123

2002 EFFECT OF DOWEL-BAR MISALIGNMENT ACROSS CONCRETE PAVEMENT JOINTS.
By **Arthur R. Smith and Sanford W. Benham** 1133

Discussion:
By L. W. Teller 1145
David J. Peery 1146
L. J. Mensch 1148
W. O. Fremont 1154
George A. Smith 1155
L. E. Grinter 1157
Arthur R. Smith and Sanford W. Benham 1160

2003 ESSENTIAL CONSIDERATIONS IN THE STABILIZATION OF SOIL.
By **C. A. Hogentogler and E. A. Willis** 1163

Discussion:
By Jacob Feld 1184
Donald M. Burmister 1185
C. A. Hogentogler and E. A. Willis 1190

2004 SOIL REACTIONS IN RELATION TO FOUNDATIONS ON PILES.
By **R. M. Miller** 1193

Discussion:
By Hibbert M. Hill 1217
George P. Stowitts 1217
George A. McKay 1219
Chandler Davis 1223
Harry E. Sawtell 1226
J. Stuart Crandall 1230
R. M. Miller 1234

2005 MEASUREMENT OF DÉBRIS-LADEN STREAM FLOW WITH CRITICAL-DEPTH FLUMES.
By **H. G. Wilm, John S. Cotton, and H. C. Storey** 1237

Discussion:
By R. L. Parshall 1254
Martin A. Mason 1257
Edwin S. Fuller 1259
Harold K. Palmer and Fred D. Bowlus 1264
Harry F. Blaney 1266
R. L. Stoker 1268
J. C. Stevens 1270
H. G. Wilm, John S. Cotton, and H. C. Storey 1271

2006 WATER TRANSPORTATION VERSUS RAIL TRANSPORTATION: A SYMPOSIUM 1279

THE VALUE OF WATER TRANSPORTATION.
By **Rufus W. Putnam** 1280

THE HIGH COST OF INLAND WATER TRANSPORTATION.
By **S. L. Wonson** 1296

No. Page

Discussion:

By George Hartley 1309
W. D. Faucette and J. E. Willoughby 1310
C. D. Bordelon 1312
J. E. Goodrich 1322
H. R. Faison 1324
Rufus W. Putnam 1330
S. L. Wonson 1333

2007 **PRE-STRESSED REINFORCED CONCRETE AND ITS POSSIBILITIES FOR BRIDGE CONSTRUCTION.**

By **Ivan A. Rosov** 1334

Discussion:

By Charles S. Whitney 1359
Karl W. Lemcke 1360
Dean F. Peterson, Jr. 1361
M. Hirschthal 1365
A. Floris 1368
A. A. Eremin 1369
Ivan A. Rosov 1370

2008 **PRACTICAL APPLICATION OF SOIL MECHANICS: A SYMPOSIUM** 1377

LEVEES IN THE LOWER MISSISSIPPI VALLEY.

By **Spencer J. Buchanan** 1378

QUABBIN DIKE BUILT BY HYDRAULIC FILL METHOD.

By **Stanley M. Dore** 1396

STABILITY OF EMBANKMENT FOUNDATIONS.

By **B. K. Hough, Jr.** 1414

SETTLEMENT OF STRUCTURES IN EUROPE AND METHODS OF OBSERVATIONS.

By **Charles Terzaghi** 1432

Discussion:

By George E. Beggs 1449
M. L. Enger 1449
R. J. Fogg 1449
Harry T. Immerman 1449
D. P. Krynine 1449
F. A. Marston 1449

2009 DESIGN OF REINFORCED CONCRETE IN TORSION.
By **Paul Andersen** 1503
Discussion:
By C. W. DEANS 1512
L. E. GRINTER 1512
BRUCE G. JOHNSTON 1516
DEAN PEABODY, JR. 1520
WALTER H. WHEELER 1521
A. FLORIS 1522
E. NEIL W. LANE 1523
A. A. EREMIN 1524
HAROLD E. WESSMAN 1525
PAUL ANDERSEN 1525

2010 ECONOMICS OF THE OHIO RIVER IMPROVEMENT.
By **C. L. Hall** 1527
Discussion:
By EUGENE L. GRANT 1553
FRED LAVIS 1556
O. SLACK BARRETT 1558
EDMUND L. DALEY AND FORREST E. BYRNS 1560
J. E. WILLOUGHBY AND W. D. FAUCETTE 1561
W. E. R. COVELL 1568
C. L. HALL 1574

2011 SOLUTION OF TRANSMISSION PROBLEMS OF A WATER SYSTEM.
By **Ellwood H. Aldrich** 1579
Discussion:
By LYNN PERRY 1602
CHARLES M. MOWER, JR. 1602
THOMAS R. CAMP 1603
HAROLD E. BABBITT 1605
C. MAXWELL STANLEY 1609
WARREN E. WILSON 1611
HAROLD K. PALMER 1611
F. KNAPP 1615
WESTON GAVETT 1616
ELLWOOD H. ALDRICH 1616

2012 AERATION TANKS FOR ACTIVATED SLUDGE PLANTS.
By **S. W. Freese** 1620
Discussion:
By NORVAL E. ANDERSON 1641
WESTON GAVETT 1644
S. W. FREESE 1646

2013 THE RELATION OF THE NATIONAL SOCIETY TO THE ENGINEERING PROFESSION: ADDRESS AT THE ANNUAL CONVENTION, SALT LAKE CITY, UTAH, JULY 20, 1938.
By **Henry Earle Riggs** 1647

2014 FINAL REPORT OF THE COMMITTEE OF THE SANITARY ENGINEERING DIVISION ON SLUDGE DIGESTION ON STANDARD PRACTICE IN SEPARATE SLUDGE DIGESTION 1662

XI

ERRATA

Transactions, Vol. 102 (1937)

Page 330, Table 1, first and second lines, instead of "$\int (y-1)\sin\phi\cos\phi\,\frac{dw}{2}$," read, "$\int (y-1)\sin\phi\cos\phi\,dw$"; and instead of "$\int (\sin^2\phi + y\cos\phi)\,dw$," read, "$\int (\sin^2\phi + y\cos^2\phi)\,dw$."

Page 331, Equation (29) and Equation (30), should read:

$$\text{“}(56.26 + 1.263 \times 15)\,R_1 - 0.155 \times 15\,R_2 = 178.956 \ldots\ldots (29)\text{”}$$

$$\text{“}-\,0.155 \times 15\,R_1 + (56.26 + 3.434 \times 15)\,R_2 = 209.652 \ldots\ldots (30)\text{”}$$

Page 331, Line following Equation (30), should read, "$R_1 = 2\,440$ lb, and $R_2 = 1\,998$ lb."

Page 331, Third line below Equation (30), should read, "$M_c = 99\,377 - 0.585 \times 2\,440 \times 15 + 0.072 \times 1\,998 \times 15 = 80\,124$ ft-lb."

Page 331, Sixth line, below Equation (30), should read,

"$f_c = \frac{M}{S} = \frac{6 \times 80\,124 \times 12}{42 \times 42 \times 42} = 79$ lb per sq in., which is about 8%, etc."

Page 331, Eleventh line from bottom should read, "$M = R_2\,a = 1\,998 \times 15 = 29\,970$ ft-lb, which is about 85% of," etc.

SELECTION OF MATERIALS FOR ROLLED-FILL EARTH DAMS

BY CHARLES H. LEE,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. T. T. KNAPPEN, PAUL BAUMANN, WILLIAM C. HILL, A. FLORIS, FRED D. PYLE, JOEL B. COX, STANLEY M. DORE, JOHN E. FIELD, WILLIAM P. CREAGER, JOSEPH JACOBS, C. H. KADIE, JR., RALPH BENNETT, R. R. PROCTOR, L. F. HARZA, AND CHARLES H. LEE.

SYNOPSIS

The traditional manner of determining suitability of material for earth dams is to exercise judgment, based upon previous experience, aided by sense testimony, such as appearance, "feel" to the hand, and possibly grittiness between the teeth. In recent years, with increase in the number and size of earth dams and the occurrence of unexpected failure, it became apparent that a more scientific method of selection was needed. The first efforts in this direction were for hydraulic-fill dams where knowledge of particle size and other physical properties was found essential as a guide to safe and permanent construction.

The recent improvements in mechanical equipment for handling earth have so reduced the cost of rolled-fill construction that the rolled-fill dam is now an economic competitor of the hydraulic-fill dam. Due to this fact and to the freedom of the rolled-fill dam from the element of treachery during construction, it is becoming a more popular type of dam. The rolled-fill dam has this disadvantage, however, that if failure occurs, it does so when the structure is in service and after it has had full opportunity to absorb water. Due to this characteristic and to the fact that practical earth-testing methods have now become more or less standardized in other lines of technical activity, such as highway construction, the present tendency in rolled-fill construction is toward the use of scientific earth-testing methods. This tendency extends both to the selection of material and to control during construction.

This paper is confined to a discussion of earth testing as an aid to the selection of materials. Pertinent fundamental principles of soil technology

---

NOTE.—Presented at the meeting of the Irrigation Division, Los Angeles, Calif., July 4, 1935, and published in September, 1936, *Proceedings*.

[1] Cons. Hydr. Engr., San Francisco, Calif.

as developed from the latest research and practice are drawn upon as a basis for conclusions. These principles are supplemented by certain research findings in concrete technology. It is shown that particle size has a direct relation to the more important properties of earth material affecting its suitability for rolled-fill dam construction. Mechanical analysis, combined with microscopic examination and, in some cases, a simple mineralogical test, is proposed as a basis for determining suitability. Before making a final selection these factors may be confirmed by tests for compaction and permeability.

REQUIREMENTS FOR SUITABILITY

The principal requirements for suitability of material for the impervious part of a rolled-fill earth dam are:

(1) Permanent stability against sloughing when saturated;

(2) Reasonable water-tightness against the maximum head of water;

(3) Workability in construction operations, involving spreading and compacting in thin layers upon the top of the embankment by the use of mechanical equipment;

(4) Insolubility of the mineral constituents composing the individual particles of the material; and

(5) Reasonable cost of handling, including excavation, transportation, spreading, and compacting.

If the dam includes a permeable down-stream section, freedom of drainage must be considered for this part.

STABILITY

The essential requirement for stablization of earth is high shearing strength resulting from a proper combination of cohesion and internal friction. This can be secured in a well-graded material through mechanical compaction to the point of maximum density by tamping, rolling, or the tramping of animals. Internal friction in an earth material is produced by the rubbing together of bulky granular particles held in contact by the forces of cohesion. The presence of coarse material, such as gravel and sand, is essential for high internal friction.

Cohesion depends upon the permanent adhesive strength due to molecular attraction of minute films of water and moist clay particles between granular particles. As an illustration, C. A. Hogentogler, Assoc. M. Am. Soc. C. E., states[3] that an almost liquid clay with cohesion amounting to about 130 lb per sq ft, when combined with a cohesionless sand will increase the supporting power of the latter from 270 lb per sq ft to 2 500 lb per sq ft. Water films in liquid or plastic soils usually have the same characteristics as water in bulk, but when the thickness of the films is reduced by drying or mechanical compaction of the soil to a semi-solid or solid state, the boiling point of film water rises, the freezing point lowers, and the surface tension increases so that the films become tough. Charles Terzaghi, M. Am. Soc. C. E., states that in thicknesses of less than 0.000002 in., water films behave like semi-solid substances[3].

---

[3] *Public Roads*, February, 1935.

The thickness of films on river sand passing a 10-mesh sieve has been estimated at 0.00002 in., and that passing a 60-mesh sieve at 0.000005 in.[4] This thickness decreases with the size of the particle, and in the case of clay is much less than for sand. As a result of this toughening of water films by the compaction of a plastic soil, the latter changes to a semi-solid or solid condition and acquires stability. If the size of the earth particles is sufficiently varied and a sufficiently high degree of compaction is obtained, this stability becomes permanent even when the material is submerged in water.

Active research in earth stabilization has been conducted during the past two decades, first in connection with highway construction, and more recently for rolled-fill dams. Research in the latter field has developed the fundamental principles of earth compaction[5], while the former among many other things has contributed a basis for the selection of materials for earth road surfaces[2]

Probably the most severe test for the stability of earth material is as a wearing surface for an earth road. Such a surface must remain unyielding and hard under pressure and the impact of the heaviest traffic; and it must be free from mud in wet weather or excessive dust in dry weather. Although the forces acting upon a dam are not concentrated as are those upon an earth road, they are of similar character. They consist principally of pressure from the weight of superimposed water and impact from waves and earthquake shock. An earth dam must also retain its stability under alternate submergence and atmospheric exposure. Because of the similarity in requirements for permanent stability in earth roads and in earth dams, the interchange of research data is admissible.

Without going into unnecessary detail, the conclusion may be stated that as the result of research, now thoroughly tested in practice, permanent stability in rolled-fill earth dams can be obtained with well-graded material compacted at a critical moisture content by use of appropriate mechanical equipment. The importance of this finding merits the following detailed consideration of both grading and compaction.

Grading.—A graded earth material is a mixture of earth particles regularly proportioned by size. The most desirable range of sizes and degree of grading differ with the type of construction and the service. For concrete aggregate a limited number of coarse particle sizes is used. For stabilized earth a wide variety of sizes, including both very coarse and very fine, is desirable. In earth-stabilization practice it is seldom possible from the economic standpoint to prepare artificially graded materials, so that natural materials must be used which conform as nearly as possible to an ideal grading.

The purpose of grading in earth stabilization is twofold: (1) To provide the mechanical properties of strength and hardness combined with cohesion and high internal friction; and (2) to secure maximum density.

---

[3] *Physical Review*, Vol. 16, 1920, p. 56.

[4] *Journal*, Am. Chemical Soc., Vol. 41, 1919, p. 477.

[5] *Engineering News-Record*, August 31, September 7, 21, and 28, 1935.

The mechanical properties of a well-graded earth result from diversity in particle size. The coarser particles held on a No. 10 sieve, including gravel, pebbles, and cobbles, may be considered as the coarse aggregate and the finer particles passing the No. 10 sieve and consisting of fine gravel, sand, silt, and clay, combined with water, may be considered as the mortar. The function of the coarse aggregate and coarse sand is to provide structural strength and hardness and a high degree of internal friction. The fine sand provides a bedding for the coarse sand. Silt is a filler which prevents the granular particles from rocking. Clay occupies the remaining voids and reduces void spaces to such small dimensions that tough connecting water films are formed which produce strong cohesion. It is thus evident that fractions of all sizes from pebbles to clay are necessary to provide a full degree of strength, hardness, cohesion, and internal friction.

High density in a graded granular material results from the voids between larger particles being occupied by smaller particles. This agrees with the fact, well known to hydraulic engineers, that the granular materials of greatest porosity are those having uniform particle size such as filter sand or clay, whereas those of least porosity have a great variety of particle size. The effect of grading upon density is well illustrated by data published[6] in 1934 in a report giving mechanical analyses and porosities for several hundred undisturbed samples of alluvial material from the South Coastal Basin of Southern California. Data for eight typical samples from this report have been plotted in Fig. 1. Samples *G*–151, *G*–145, and *G*–107 con-

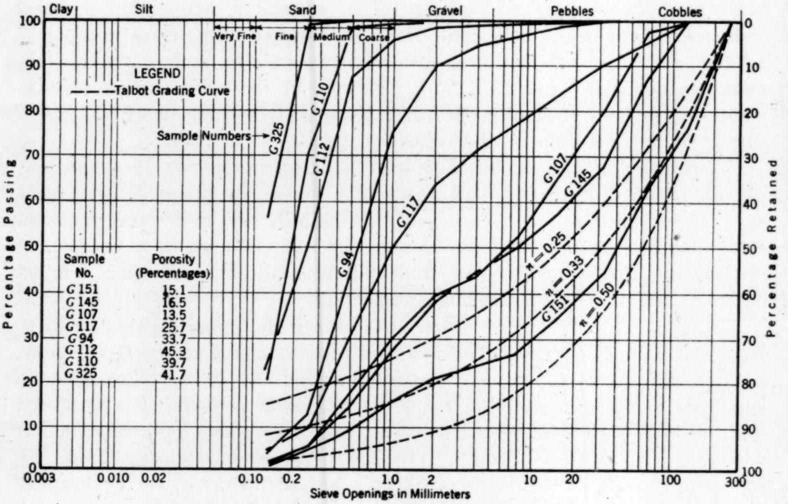

FIG. 1.—RELATION OF POROSITY TO GRADING.

---

[6] *Bulletin No. 45*, Div. of Water Resources, State of California, South Coastal Basin Investigation, "Geology and Ground-Water Storage Capacity of Valley-Fill", 1934.

tain all sizes from large cobbles to fine sand, with a preponderance of coarse sizes and regular gradation of fine particles. The porosity of these three samples averages 15 per cent. Samples *G*–112, *G*–110, and *G*–325 are composed of fine and medium sand. These samples have porosities averaging 42%, and those with the intermediate ranges of sizes represented by Samples *G*–117 and *G*–94 have porosities between these two extremes.

Curves plotted to a semi-logarithmic scale which flatten out toward the fines and are concave upward represent well-graded material, whereas those which are flat in coarse material and become steep toward the fines, or are nearly straight and vertical, represent uniformity in particle size. The progressive decrease of porosity with grading is strikingly shown in Fig. 1.

The ideal grading for maximum density has been thoroughly investigated in the well-known experiments on aggregates and concrete by Sanford E. Thompson, M. Am. Soc. C. E., and the late William B. Fuller, M. Am. Soc. C. E., in 1903[7], supplemented by those of A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., and F. E. Richart, M. Am. Soc. C. E., in 1919 to 1923[8]. These experiments show that regular grading produced greater density than irregular grading, and that maximum density resulted from a relatively coarse grading As a result of his experiments, Professor Talbot developed a general grading equation which may be written, as,

$$p = \left(\frac{d}{D}\right)^n \text{ ....(1)}$$

in which p = the proportion by weight passing a given screen or sieve opening; d = size of opening; D = maximum particle size; and n = an exponent. These experiments were conducted on graded mixtures with several maximum sizes of aggregates and values of n varying from 0.24 to 1.20, representing mixtures varying from extremely fine gradings to extremely coarse. Characteristics of gradings for typical values of n, as shown by these experiments, are as follows:

For $n = 1.0$, the curve of Equation (1) is a straight line when plotted to natural scale and represents a very coarse grading;

For $n = 0.5$, the curve is a parabola (natural scale) and represents a medium grading corresponding with the Fuller-Thompson parabolic grading (provided sieve holes are of the same shape); it produces maximum density of mixture for aggregates having a maximum size of approximately $\frac{1}{4}$ to $\frac{1}{2}$ in.

For $n = 0.33$, the curve is more nearly an ellipse (natural scale) and represents a fine grading with maximum density of mixture (porosity, 20 to 22%) for aggregates having a maximum size of from 1 in. to 2 in.; and,

For $n = 0.25$, the curve also resembles an ellipse and represents a very fine grading with maximum density of mixture for aggregates having a maximum size of from 4 to 6 in.

The Talbot grading equation, although developed for use with concrete aggregates, is applicable to earth mixtures and may be used as a criterion for density in the selection of natural earth material for rolled-fill dams This is shown by the following two examples:

---

[7] *Transactions*, Am. Soc. C. E., Vol. LIX (1907), p. 67.

[8] *Bulletin No. 137*, Eng. Experiment Station, Univ. of Illinois, October 15, 1923.

Example 1.—Grading curves with 10-in. (256-mm) maximum size of particle, when plotted in Fig. 1 correspond in shape with the mechanical analysis curve for Sample *G*–151, the curve for $n = 0.33$ corresponding most closely in position. A similar plotting with a 5-in. (128-mm) maximum size shows that the grading curve for $n = 0.33$ also corresponds generally in shape and position with the mechanical analysis curves of Samples *G*–145 and *G*–107. These three samples all have high density (average porosity, 15%). Similar plotting against the mechanical analysis curves of five other samples, all of which have lower densities, shows no similarity in shape or position. In other words, the Talbot grading equation automatically designates the material of highest density.

Example 2.—Based upon extensive experience, the United States Bureau of Public Roads recommends the following size specification for mixtures having sufficient stability for earth road surfacing[9]:

Sieve.	Percentage passing by weight.	Sieve.	Percentage passing by weight.
1-in.	100	No. 10	40 to 65
¾-in.	85 to 100	No. 40	25 to 50
No. 4	55 to 85	No. 270	10 to 25

The soil mortar in this material passing the No. 10 sieve has a composition as shown in Table 1[10]. These limits have been plotted in Fig. 2, together with grading curves for the corresponding maximum particles sizes. Here, again, there is found to be a very close agreement in shape and position, the curve for $n = 0.33$ lying closest to the mechanical analysis curve for the mixture, and $n = 0.50$ closest to the corresponding curve for the soil mortar. This shows that the Talbot grading curves for maximum density designate an earth mixture found to be satisfactory for the surfacing of earth roads.

TABLE 1.

Fraction	Diameter, in millimeters	Percentage by weight
Clay	Less than 0.005	5–10
Silt	0.005 to 0.05	10–20
Sand, total	0.05 to 1.0	70–85
Sand, coarse	0.5 to 1.0	45–60
Average effective size	0.01	.....
Uniformity coefficient	Greater than 15	.....

From these and other studies it is concluded that the Talbot grading curve with values of n between 0.25 and 0.50 may be used as a criterion for high density in the selection of natural material for rolled-fill dams.

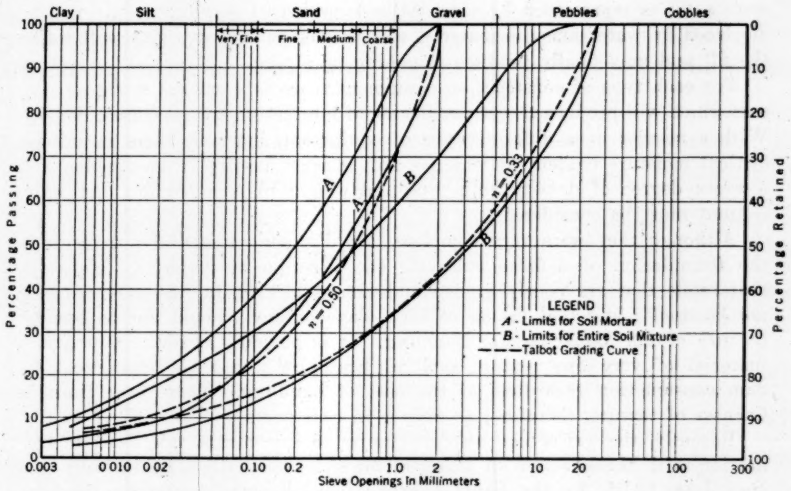

FIG. 2.—SIZE SPECIFICATION OF MIXTURES RECOMMENDED BY U. S. BUREAU OF PUBLIC ROADS FOR SURFACING EARTH ROADS.

COMPACTION

The purpose of compaction of earth material is to bring the soil particles into uniform close contact. This has three effects: First, it increases the mechanical bond by interlocking the individual grains; second (and, of much more importance), it decreases the thickness of connecting water films, thus greatly increasing their adhesive force; and third, it partly expels air which, if retained, would ultimately be replaced by water, thus increasing the thickness of water films and decreasing cohesion. The net effect of compaction is to increase density and produce permanent cohesion.

In open areas earth is compacted by spreading it in thin layers and rolling it with trucks and heavy flat rollers, or kneading and rolling it with sheepsfoot rollers. In restricted spaces the material is made compact by tamping.

The fundamental principles of soil compaction and their application to rolled-fill earth dams in the selection of materials and control during construction have been thoroughly developed by R. R. Proctor, M. Am. Soc. C. E.[11] His work shows that in a given earth material and for each particular method of compaction, there is a critical moisture content at which maximum density is attained. Higher water content results in increased plasticity, larger voids, and less density, until a point is reached at which equipment will not be supported. A lower content may produce a fill of greater apparent stability with little or no plasticity, but one having a greater void volume and less density. The decreased water content and increased void volume in such a fill is represented by air. After a period of service the air will be displaced by water and the material will become saturated. This will soften the fill and may finally produce sloughing or piping.

---

[11] *Engineering News-Record*, August 31, September 7, 21, and 28, 1933.

For each type of construction equipment there is a critical moisture content which will produce the proper degree of lubrication for maximum density. With a heavier or a different type of equipment, however, there is a lower critical moisture content at which a still greater density is attainable. For a given degree of density both type and weight of construction and water content must be considered.

Although they were very complete, Mr. Proctor's tests did not result in the formulation of definite rules for the selection of material. He states that "soils that are poorly graded and almost lacking in fine particles cannot be used"; and that "those of high clay content" should not be selected because of the higher cost of handling. It is obvious, however, that a clay material of very fine texture such as bentonite would be impractical for dam construction regardless of the cost of handling. There is a limit in fineness of texture, therefore, as well as in coarseness.

Recently, the writer had an opportunity to investigate this limit in connection with the selection of material for the Coyote Dam being built near San Jose, Calif., by the Santa Clara Valley Water Conservation District. Among the materials selected for testing was one of ancient lacustrine origin. With the passage of time this material had become indurated to a siltstone, was subsequently elevated, and, finally, became softened by weathering, to a depth of more than 12 ft. It was located conveniently for handling and in preliminary field examination had been favorably considered for use in rolled-fill construction of the impervious section of the dam. When samples from the weathered zone were subjected to mechanical analysis by the sieve and hydrometer method, difficulty was experienced in breaking the material down to ultimate particle size during the ordinary period of stirring, even with pre-treatment. Microscopic examination of particles after stirring, as held by Tyler standard sieves from No. 48 to No. 270, showed numerous rounded aggregations of silt and clay representing particles of original siltstone. These particles were soft and more or less plastic, and after drying crushed easily under the thumb-nail. With long-continued further stirring these aggregates finally broke down into particles of silt and clay size. It was also found that larger unbroken pieces of the original material absorbed water rapidly and softened so as to crush easily between the fingers.

The question then arose as to whether this material would act in the completed fill as a mixed sand, silt, and clay, which was the constituency as indicated by field examination and standard mechanical analysis, or whether it would act in accordance with ultimate particle sizes as obtained by prolonged stirring. The latter indicated a material of finer texture than that of the borrow-pit samples from Alexander Dam, in Hawaii, and closely resembled the core samples from that dam. The experience with such fine material for rolled-fill construction both in the Islands and elsewhere has been very unsatisfactory[13]. This is illustrated by the clause often placed in specifications for rolled-fill dams, requiring exclusion of adobe soils. It was determined, therefore, to make a series of compaction tests, including materials from very fine to very coarse texture, and to observe especially the extent to which air remained in the compacted samples. Ten samples were selected for testing as described in Table 2. Mechanical analyses of samples were made by the standard hydrometer and sieve method as developed by the

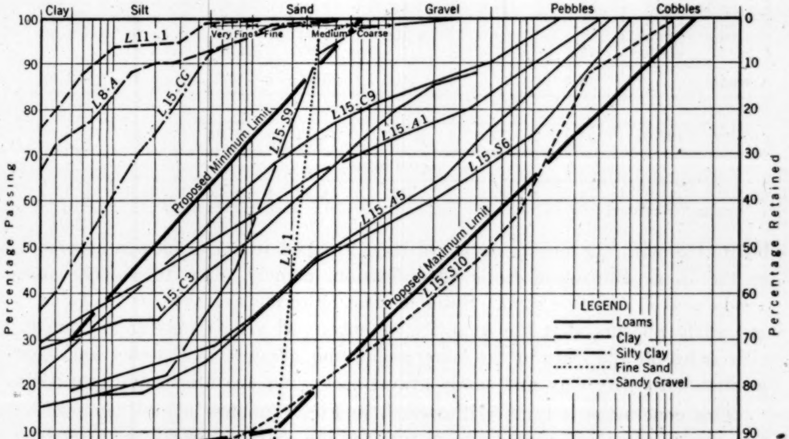

FIG. 3.—MECHANICAL ANALYSIS OF SAMPLES TESTED IN COMPACTION.

U. S. Bureau of Public Roads[13]. In the case of Sample *L*15-Coyote *G*, composed largely of siltstone, the suspension was shaken for 17 hr on a revolving wheel and correction was made after a microscopic examination and a count of undigested siltstone particles in the various screen fractions. The results of mechanical analyses are shown graphically in Fig. 3.

Compaction tests were made on all samples in conformity with the standard laboratory method developed by Mr. Proctor, the results being listed in Table 3. The samples have been arranged in this table in order of texture, beginning with the finest, and have been grouped into five classes according to the U. S. Bureau of Soils Classification, namely, clay, silty clay, loam, sandy gravel, and fine sand. Summarizing by group averages, as in Table 4, it clearly appears that the quantity of entrapped air at maximum compaction is by far the least in the loam group, and greatest in the clay and sand groups, with silty clay and sandy gravel occupying an intermediate position.

TABLE 3.—SUMMARY OF COMPACTION TESTS

Sample	AT MAXIMUM COMPACTION				AVERAGE AIR CONTENT, WITH WATER CONTENT GREATER THAN AT MAXIMUM COMPACTION		AIR CONTENT AT MAXIMUM COMPACTION

Fine sand	15 to 0*	11.0	40.2	20.3	50.5	12.30	112.0

* Silt and clay.

equivalent water content, in percentages of dry weight. Each texture group has a distinctive type of compaction curve and occupies a distinctive area upon the diagram, thus indicating differing physical properties. Compaction curves for clay, silty clay, and sand groups, are farthest from the line of zero air voids and lowest in dry weight at maximum compaction; and they have very flat peaks. The loam group is the closest to the line of zero air voids, has the greatest dry weight, and its curves have very sharp peaks. The sandy gravel curve, although having a sharp peak, and dry weight similar to those

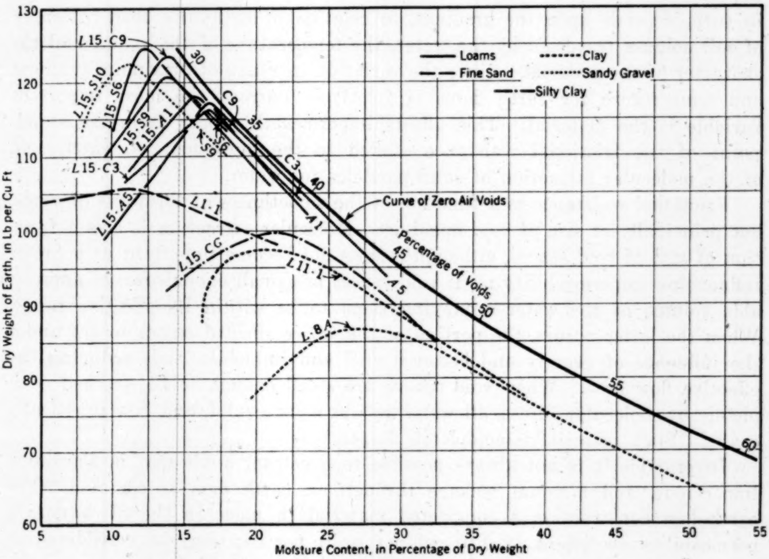

FIG. 4.—CURVES OF COMPACTION AND ZERO AIR VOIDS.

for loam, is farther from the curve of zero air voids. The superiority of loam from the standpoint of dry weight and minimum air voids is apparent.

Expressing this superiority in terms of mechanical analysis, the data in Figs. 3 and 4 indicate that for permanent stability of compacted earth material the clay fraction should not exceed 30 to 35%; nor should it be less than 3 to 15%, the latter limits depending on the degree to which the material is graded.

With regard to the disintegrated siltstone (Sample *L*15-*CG*), it appeared that the air content at maximum compaction expressed as equivalent water was three times that of the next nearest available material represented by Sample *L*15-*C*9 (Fig. 4) and that it lay in the clay group in Fig. 3. Due to the large percentage of air voids, even under ideal conditions of handling in the laboratory, and the probability of non-uniform compaction in the fill due to difficulty in handling, the siltstone was discarded for use in the main structure of the dam.

IMPERMEABILITY

The water-tightness of an earth dam is determined by the degree of impermeability of the material as compacted in the fill. This impermeability, in turn, depends upon the gradient, or relation of hydraulic head to length of soil column traversed by the water, the temperature of the water, and the character of the material. Since the variation in range of maximum gradient and temperature for earth dams is relatively narrow, the most important variable is the material. This affects impermeability both from the standpoint of the frictional resistance offered to the movement of water, and of the molecular attraction of solid particles for water.

Frictional resistance is a function of the smoothness of the walls of voids, but principally of size of void openings. Molecular attraction is also a function of size of void spaces, although it does not become important as a factor influencing impermeability until void spaces are small enough for an appreciable volume of the water occupying them to be within its effective range. When the latter occurs, the portion of the water affected ceases to act under the influence of gravity and becomes stiff and immobile, thus reducing the effective flow area. When void spaces are small enough to be spanned completely by molecular forces, all water acts as a semi-solid, and flow practically ceases. Such material is completely impervious.

In practice it is not always possible to construct a fill that is absolutely impervious, and nominal leakage through an earth dam is common. For earth-dam construction a compacted material in place in the fill having a permeability coefficient of 0.10 gal per sq ft per day may be considered as practically water-tight. The permeability coefficient is defined herein as the quantity of water, in gallons per day, flowing through a section of material perpendicular to the direction of flow and 1 sq ft in area under a hydraulic gradient of 100% and temperature of 60° F. A permeability coefficient of 0.1 as thus defined is equivalent to a percolation rate, as defined by Proctor, of 4.86 ft per yr. For an earth dam of uniform construction 200 ft in height, and 650 ft in average width, with a slope of 1 on 2.5, a top width of 20 ft, and a 10-ft free-board (assuming the water-table just below the surface of the ground at the down-stream toe), a permeability coefficient of 0.1 gal per sq ft per day represents a leakage, when full, of approximately 2 600 gal per day, or 0.004 cu ft per sec. Under certain conditions permeability coefficients exceeding 1.0 gal per sq ft per day might be allowable.

The recent standardizing of methods for measuring and expressing permeability make possible a correlation of mechanical analysis and permeability coefficients. Based upon the study of numerous permeability tests made by the Pacific Hydrologic Laboratory, and Hydrologic Laboratory, Water Resources Branch, United States Geological Survey, the statement can be made that regularly graded material having a degree of fineness sufficient to include at least 3% of clay, or ungraded material containing at least 25% of clay, when thoroughly compacted, is practically water-tight. Partly or poorly graded materials may be impervious if they contain less than 25% and

* The first three samples were graded approximately; the remainder were not graded.

more than 3% of clay, the quantity depending upon the departure from regular grading. These conclusions are illustrated by mechanical analysis and permeability data for a wide variety of samples as presented in Fig. 5 and Table 5.

Samples *L*15-*S*10 and *L*15-*S*6 closely approximate regular grading, the mechanical analysis curves being roughly parallel to the regular grading curve for $n = 0.33$ (see Fig. 5). Sample *L*12-2, which conforms more nearly to a straight line, also has a rough grading, although not to the same degree as the other two. Sample *L*15-*S*10, which approaches nearest to the ideal curve, contains only 6.5% of silt and clay and approximately 3% of clay. Its permeability coefficient is 0.01. Sample *L*15-*S*6, which is less well-graded, has a permeability coefficient of 0.034, and a clay content of 17. Sample *L*12-2, which is poorly graded and has only 9% of clay, has a permeability coefficient of 0.5.

All other samples listed in Table 5 are ungraded. Samples 3 and 1, with 57% and 29% of clay, are impermeable; but Sample 9, with 17.3% of clay and 53.1% of silt, has a coefficient of 1.6; and Sample 10, with 23% of clay and 21% of silt, has a coefficient of 2.28. Other samples with less than 25% of clay have larger and larger coefficients as the size of the particles increase. Sample 47, with no clay and 54.7% of gravel, has a coefficient of 6 200, as compared with the coefficient of 0.01 for the graded sample, *L*15-*S*10, with 3% of clay and 68.6% of gravel.

These data illustrate in a striking manner the importance of grading, and confirm the statement that 3% of clay in graded, and 25% of clay in ungraded, material is sufficient to render it impervious.

In passing, it should be noted in Fig. 5 that the mechanical analysis curves for graded materials are concave upward, steep in large sizes, and flattening out toward the fines; whereas ungraded materials are convex upward, flat in large sizes, very steep in intermediate sizes, and either steep or flattening out in very fine sizes. These characteristics are useful when interpreting mechanical analyses with reference to permeability.

WORKABILITY

A workable material is one that can be compacted readily into a fill of uniform texture and high density by the use of mechanical equipment. In order to fulfill this requirement the material must compact easily, and not be so harsh as to cause the equipment to wear out rapidly, nor so sticky as to delay the spreading and rolling operations. These qualities are controlled largely by the texture of the material.

Materials that compact most easily are composed of well-graded gravel and sand with a silt and clay percentage of from 10 to 25 to supply lubrication. The application of proper moisture percentage for maximum density also facilitates compaction.

Harshness is produced by coarseness of grading either with or without the maximum size of particles, such as large pebbles and cobble-stones. The maximum allowable size of stone varies with the thickness of the layers and the type of rolling equipment, whether flat or sheepsfoot. With 6-in. layers, cobbles should not exceed 5 in. in diameter. The allowable coarseness is also related to the type of equipment. As a general practice, values of n in Equation (1) should not exceed 0.50.

Stickiness is produced by high clay content. The allowable quantity can be varied, depending upon the type of equipment and time at which moisture is applied. In general, clayey material with a moisture percentage giving maximum density in compaction is not sticky in handling, provided the moisture is uniformly distributed through the mass. Clayey material is very slow to absorb water, however, and if worked immediately after sprinkling may be very sticky, even if the proper quantity of moisture has been added. This is due to the fact that the moisture content of the exposed surface with which equipment comes in contact is temporarily far greater than the critical moisture. If several hours are allowed after sprinkling for complete absorption and distribution of moisture, no difficulty may be experienced.

There are also other methods of overcoming stickiness which do not involve delay. The sprinkling of the rolled surface of the previous layer immediately in advance of dumping material for the new layer has proved successful. The exposed surface of the new material remains comparatively dry during the process of spreading and initial rolling, attaining an ultimate moisture content not in excess of the critical moisture after the water has moved slowly upward through the layer by capillarity. Another method is to sprinkle the material in the bank before excavation if natural moisture is much below the critical. In some instances, rainfall will moisten the soil in the bank or borrow-pit to a sufficient depth to bring the moisture content up to the percentage desired.

INSOLUBILITY

An obvious requirement for permanency in an earth dam is that the substances composing the individual earth particles must not be soluble. Gypsum and lime are frequently encountered in sedimentary rock formations and may appear in alluvial deposits either as incrustation or nodules occupying voids, or as particles of the original material. Although these substances are not as readily soluble as rock salt or alkali incrustations, percolating water will dissolve and remove appreciable quantities in time, rendering the fill more porous and threatening its stability and water-tightness.

The presence of soluble substances can usually be detected by simple observation, aided sometimes with a pocket microscope or an acid test.

COST OF HANDLING

Other requirements having been satisfied, the cost of handling the material is of final importance. Handling includes the operations of excavation, transportation, spreading, and rolling. Important factors affecting the cost of material taken from a given bank or borrow-pit are the distance and relative elevation from the dam, the quantity of satisfactory material available with reference to the volume of the dam, and the clay content of the material. The relation of these factors to cost is well understood and needs no discussion.

Mechanical Analysis as a Basis for Selection

Of the five requirements for judging the suitability of material for rolled-fill earth dam construction (cited previously), the three most important are stability, water-tightness, and workability. There is an intimate relation between each of them and the mechanical composition of the material. Stability and water-tightness are both secured as a result of regular grading of particle sizes and compaction of material; grading is entirely a matter of mechanical composition. In order to be effective permanently, compaction necessitates the establishment of limits for the clay and silt fractions. Workability also involves limits, both for fine and coarse fractions. This suggests the possibility for using mechanical analysis as a preliminary basis for the selection of material.

Examination of mechanical analysis curves for a variety of materials, such as those shown in Figs. 1 and 5, discloses great divergence in slopes, curvature, and terminal points. Even between fixed terminal points an almost infinite number of curves are possible. Such curves represent material varying from well-graded to uniform size of particle, from dense to very porous, and from impermeable to highly permeable. As these extremes result not only from variation in particle size, but also from variation in grading, it is apparent that if any method of selection based on mechanical analysis is to be successful, it must include limits of size as well as of departure from regular grading. If specified from the graphical standpoint, this means that in referring to the mechanical analysis diagrams, limits in shape and slope of curvature must be considered as well as limits in area. To establish such limits, it is proposed, first, to set up limits of particle size for coarse and for fine materials; and, second, to prescribe curvature limits based upon both degree and fineness of grading. The establishment of a size limit for coarse materials has already been attempted[14] by E. W. Lane, M. Am. Soc. C. E., but, to date, no attempt has been made to establish limits for size of fine materials, nor for degree and fineness of grading.

Before proceeding to details, it should be noted: First, that the terminal points of a mechanical analysis curve indicate size limits; second, that the slope of a mechanical analysis curve indicates the fineness of grading as numerically represented by the value of n in Equation (1); and, third, that the shape of a mechanical analysis curve indicates the degree of grading, if any, as numerically represented by departure from Equation (1). It thus appears that two sets of limiting curves are desirable, one applying to regularly graded materials and the other to ungraded materials. Between these limits will lie the poorly graded materials. Figs. 6 and 7, with Table 6, illustrate the range of the proposed specifications for limiting curves for graded and ungraded materials. (See, also, the revision of Fig. 6 presented as Fig. 23 in the closing discussion.)

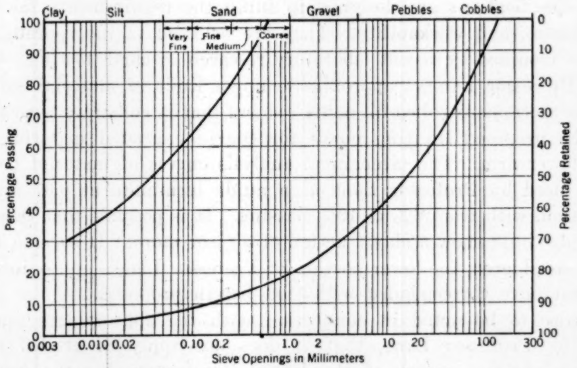

FIG. 6.—PROPOSED LIMITS IN MECHANICAL ANALYSIS FOR GRADED MATERIALS SUITABLE FOR IMPERVIOUS SECTIONS OF ROLLED-FILL EARTH DAMS

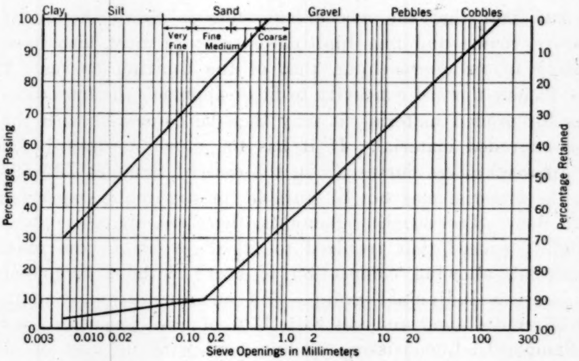

FIG. 7.—PROPOSED LIMITS FOR UNGRADED MATERIALS SUITABLE FOR IMPERVIOUS SECTIONS FOR ROLLED-FILL DAMS

TABLE 6.—PROPOSED LIMITS FOR GRADED AND UNGRADED MATERIALS

Class of material	Terminal Points for Curves (See Figs. 6 and 7)		Graded materials; values of n in Equation (1)	Ungraded materials; Remarks
	Maximum particle size, in millimeters	Minimum percentage of clay ‡		
Coarse	128*	3 to 5	0.33	Straight lines from terminal points to 10% less than 0.15 mm.
Intermediate	128* to 0.6†	3 to 30	0.33 to 0.25	Approximately parallel to the fine limit and the upper arm of the coarse limit, but not crossing the lower arm of the coarse limit.
Fine	0.6	30	0.25	Straight line.

* 5 in. † No. 28 mesh. ‡ Particle size, 0.005 mm.

These specifications are designed to fulfill the requirements for stability, water-tightness, and workability. They are believed to incorporate standard practice as modified by recent laboratory research in earth testing. Comparison with Professor Lane's "approximate upper limit of material suitable for impervious sections of rolled-fill dams", shows that it coincides with the upper arm of the proposed limiting curve for coarse ungraded material, but not with the lower arm. The mechanical analysis curves of material from existing dams used by Professor Lane as a guide terminate at 0.07 mm in the sand fraction, with from 6% to 10% passing. It is possible that these curves, if extended, would show a clay fraction of 3%, or more. If so, and this fraction were considered, the lower portion of Professor Lane's approximate upper limit might have corresponded with that herein proposed.

It is also to be noted in connection with the approximate upper limit proposed by Professor Lane, that it does not apply to graded materials. Mechanical analysis curves of the latter, satisfactory for the construction of rolled-fill dams, may lie beyond this limit in the sand, gravel, and pebble fractions, provided such material contains at least 3% of clay.

In applying the proposed limits to determine the suitability of a material, it is not sufficient that the mechanical analysis curve should lie between the respective coarse and fine limiting curves; it must also have a shape corresponding to, or approaching, that of the limiting curves. If it does not have sufficient upward concavity to fit or approach the curvature of limiting curves for graded material, it may then be compared with the limiting curves for ungraded material. If it has too much downward concavity to follow or approach these curves, as in the case of Samples *L*15-*S*9 and *L*1-1 in Fig. 3, the material may not be suitable for use in the impervious part of a rolled-fill dam. The deciding factor is, therefore, the clay content, which should slightly exceed that required to fill the voids in the granular part of the material, allowing compaction to occur without completely closing the gaps between individual grains. As an illustration, Sample *L*15-*S*9, composed of graded sand and silt with 17% of clay, is entirely satisfactory, whereas Sample *L*1-1, consisting of fine sand with no clay or silt, is not suitable.

The selection of material from mechanical analysis data, although believed to be practical, is more or less preliminary in character at present and subject to modification as the result of more positive tests, such as compaction, permeability, etc.

These criteria for selection of earth material for rolled-fill dam construction are presented in the hope that they will bring forth discussion and additional data, from which may be evolved a basis for preliminary selection generally acceptable to the profession.

DISCUSSION

T. T. **Knappen**,[15] M. Am. Soc. C. E. (by letter).—There are certain fundamental conceptions essential to the design of a dam. At a particular site an engineer may consider some form of concrete structure or a structure built of earthen materials, which may include rock. In considering an earth dam, the engineer has a choice between dry and hydraulic methods of construction. For the dry method practice has standardized on the placement of material in thin layers, with suitable compaction by rollers of various types, or by power-tamping or vibrating equipment. For the economical design of an earth dam, it is essential, first, to utilize all materials from required excavations; and, second, to construct the remainder of the dam from the materials available in the vicinity. The greatest economy generally results from the use of materials closest to the site.

In this paper, the author has based his selection to a large extent on grain-size distribution. This is a logical method in the preliminary stages. In Figs. 6 and 7, he has given the proposed limits for materials suitable for impervious sections of rolled-fill earth dams. The writer agrees that, in general, material falling within these limits will be satisfactory. However, it is entirely possible to use materials that do not come within these limits. First, considering materials that are finer than the upper curves on these two diagrams, although such materials may be somewhat difficult to handle and may be structurally somewhat unstable, they may furnish, nevertheless, an excellent impervious core for a dam embankment. In the computation for such cases the outer shell must be depended upon for structural strength. The dam may be analyzed by a method recently outlined by the writer.[16]

Considering the two lower curves which represent the limit of permeability, it is perfectly possible to use materials of greater permeability than those indicated. It may be conceded that an earth dam can be safely designed and built, provided it is properly designed, with the expectation of a large leakage. The approximate upper limit, indicated by the author, of 1 gal per sq ft per day, with an hydraulic gradient of 1 is extremely conservative. This is equivalent to a value of k in Darcy's formula,

$$Q = k\,i\,A\,t \qquad (2)$$

of 0.4×10^{-4} cm per sec. In the case illustrated, the author deduced that the leakage would be 0.004 cu ft per sec with a coefficient of 0.1 gal per sq ft per day. From a structural standpoint, a leakage of a thousand times this amount is not necessarily excessive with proper design. In other words, a permeability coefficient of 100 gal per sq ft per day might be satisfactory in centimeter-gram-second units (40×10^{-4} cm per sec.) It would seem to the writer that the upper limit of permissible seepage is largely a matter of economics. The cost of reducing the leakage should be balanced against the value of the water saved.

---

[15] Associate, Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

[16] "Calculation of the Stability of Earth Dams", presented before the World Power Conference, Washington, D. C., September, 1936.

In the case of flood-control dams, or dams at which constant releases are required, it may be of no economic consideration whatever. In such cases, it becomes merely a structural problem of designing the embankment to pass the leakage safely. Recently, the writer had occasion to design a dam for which the estimated leakage through the foundations, with water at spillway level, amounted to 50 cu ft per sec. In such a case, it would be unwarranted to go to great expense to obtain an impermeable embankment.

The writer cannot agree with the author in eliminating the siltstone (Sample *L*15–*CG*, Table 2) for use in the Coyote Dam on the basis of the information set forth in the paper. It would appear that this material could have been used advantageously at least in the center one-fourth of the embankment, with resulting economy. Certainly, more exhaustive tests to determine its structural nature in terms of cohesion and angle of internal friction under saturated conditions in the embankment should have been made before discarding its use in the center section of the dam, and there is a possibility that it might have been used safely for a large percentage of the embankment.

In the paragraph following Fig. 4 the author makes the statement that "the data in Figs. 3 and 4 indicate that for permanent stability of compacted earth material the clay fraction should not exceed 30 to 35%; nor should it be less than 3 to 15%, the latter limits depending on the degree to which the material is graded." Based on this statement, the engineer having such a material as Sample *L*15–*CG* would be precluded from constructing a dam, whereas it can be used with proper design. A combination of Sample *L*15–*CG*, or even Sample *L*8–*A* for a core and Sample *L*15–*S*10 (or, preferably, a coarser material) for the shells will result in an excellent and economical dam, possibly a better one than that built uniformly with Sample *L*15–*C*9.

There are few materials that cannot be used successfully, to some extent, in the construction of earth dams. The materials approved by the author may be used with little additional investigation, but for true economy in difficult designs every analytical resource of the science of soil mechanics should be called upon to produce a design utilizing the closest available materials to produce a safe and enduring structure. The writer knows of more than one dam that could never have been built had the author's limitations been applied.

PAUL BAUMANN,[17] M. AM. SOC. C. E. (by letter).—Due to the rapid exhaustion of suitable dam sites it is believed that, in the future, rolled-fill dams will gradually exceed masonry dams in number. Hence, this paper is particularly timely and valuable.

The author points out five principal requirements for suitability of material for the impervious part of a rolled-fill earth dam. He further stresses the importance of grading the material to satisfy these requirements. This tends to imply that unless material which conforms to the specifications of gradation is available in the vicinity of a site chosen for a rolled-fill dam, such a dam cannot be built. The writer's experience, acquired during the construction of San Gabriel Dam No. 1, does not substantiate this contention.

---

[17] Junior Asst. Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

Material that is not initially suitable for rolled-fills, because of gradation defects, can be made suitable by proper compaction.

Two widely different types of materials have been placed and compacted in San Gabriel Dam No. 1: A clayey sand or loam in Zone 2; and quarry-run material which has passed through a 6 by 9-in. grill in Zone 3. The location of these zones is shown in Fig. 8 which is composite cross-section of the dam.

FIG. 8.—COMPOSITE MAXIMUM SECTION, SAN GABRIEL DAM NO. 1.

In order to illustrate the comparative initial and final gradation, a typical screen analysis is shown for each of the two materials in Figs. 9 and 10. Whereas, the fineness modulus of the wet clayey sand is 1.17 for the average sample before compaction and is not changed materially through compaction, the average fineness modulus of the quarry-run material is 5.72 before compaction and 5.06 after compaction; and, although the material in Zone 2 conforms approximately to what might be called standard specifications for

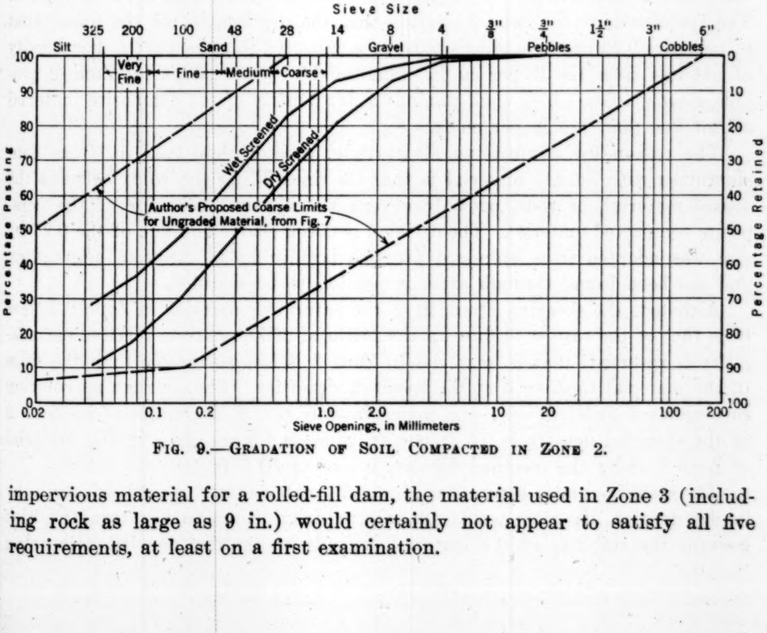

FIG. 9.—GRADATION OF SOIL COMPACTED IN ZONE 2.

impervious material for a rolled-fill dam, the material used in Zone 3 (including rock as large as 9 in.) would certainly not appear to satisfy all five requirements, at least on a first examination.

As a matter of fact, with the rolling equipment used at San Gabriel Dam No. 1, which was specially designed for the job, material in Zone 3 requires less effort for compaction than material in Zone 2; that is, whereas twelve trips are required to produce the specified compaction in Zone 3, between sixteen and twenty trips are required to produce such compaction in Zone 2. The specifications for Zone 3 provide that the dry density of the fines (that is, particles 0.25 in., or smaller) must be compacted so as to have a dry density of not less than 120 lb per cu ft., whereas the specifications for Zone 2 provide a compaction which shall produce a dry density of the composite material of not less than 115 lb per cu ft.

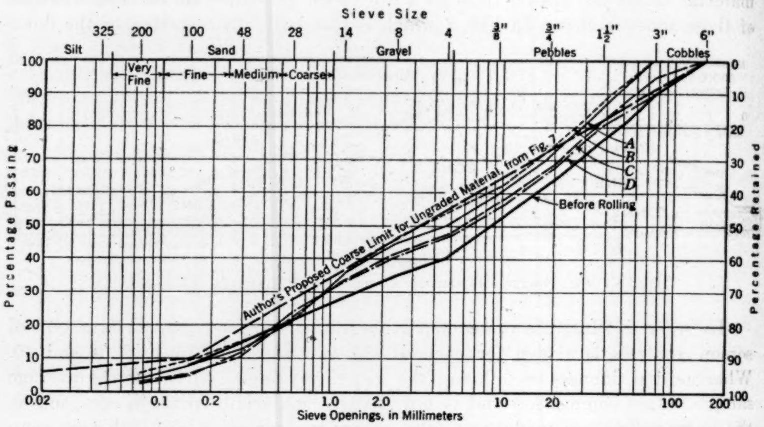

FIG. 10.—EFFECT OF ROLLING (TEN TRIPS WITH A 12.1-TON ROLLER) ON GRADATION OF MATERIAL PASSING A 6 BY 9-FOOT GRILL.

The reason for eliminating all particles greater than 0.25 in. from consideration with Zone 3 material is that the fines filling the voids between the coarse material, or rock, actually govern the physical behavior of the composite compacted material. The division between coarse and fine of the 0.25-in. size was adopted from standard practice pertaining to concrete aggregates, and has been found through experimentation to be justified.

Although the shearing strength of the saturated material in Zone 2 is less than that of the saturated fines in the material of Zone 3, the relative permeability is reversed; that is, material in Zone 2 is less permeable than the fines in the material in Zone 3 at the specified densities. The average percolation rate under a gradient of 1 and approximately 60° F for material in Zone 2 at the specified density is 0.5 ft per yr, whereas for the fines in the material of Zone 3 under the specified density, it averages 1.5 ft per yr.

The stability under saturation of any fill material is governed primarily by its dry density. In other words, the internal friction or shearing strength which governs the stability of the material depends on the dry density. Shearing tests on saturated fines of the material in Zone 3 have shown shearing strengths varying from 22 lb per sq in. for a vertical load of 25 lb per sq in., to a shearing strength of 525 lb per sq in. for a vertical load of 1 200 lb per sq in. Due to this governing factor (that is, the dry density of the material), it is quite obvious that the conditions for stability of a hydraulic-fill dam under saturation and the conditions for stability of a rolled-fill dam under saturation are necessarily at variance. With the hydraulic-fill process it is not possible to create an initial dry density of the material in excess of a relatively low limit, whereas with the rolled-fill, or mechanically compacted-fill process, the attainable dry density is approaching that of the solid material. The composite fill in Zone 3, for example, in place, has an average weight of 150 lb per cu ft., which indicates that it is approaching the physical state of an artificial stone. The specific gravity of the material used in Zone 3 averages 2.78, which means a solid weight of 173.5 lb per cu ft. The average dry weight of the composite material in place was found to be 143 lb which would mean that the porosity of the composite fill in Zone 3 is approximately 17.5 per cent. Typical results of density tests are shown in Table 7.

TABLE 7.—SOIL CHARACTERISTICS SUPPORTING THE CURVES IN FIG. 12

2....	133.9	118.2†	13.3	3.2	20	2.79	36.3

* Fines. † Composite.

The reason for the small porosity and, consequently, the small permeability of material in Zone 3, is the breakdown that occurs during the rolling of the material as is evident from Fig. 10. The effect of compaction relative to breakdown for variable moisture is further illustrated in Fig. 11. Fig. 11(*a*) shows the increase in breakdown due to twenty-five hard tamps with a 5.5-lb tamper over the breakdown due to five 4-in. drops. The maximum, additional breakdown coincides with the peak of compaction.

Furthermore, the initial compaction of granular material and the breaking strength of the particles are governing factors in regard to its stability under saturation, because the water which, in a saturated condition, completely fills the voids, cannot escape in case of sudden compression of the material, but will, itself, be put under stress. Hence, if the compression is of sufficient magnitude to crush the parts in contact between particles, the shearing strength may readily drop to a critical value due to load being transmitted through water on the one hand and to the production of very fine particles or flour caused by the crushing on the other. These fine particles, after crushing, will naturally mix with the water and will form slime which tends to lubricate the contact surfaces and minimize internal friction.

In regard to cohesion due to the surface tension of water which is always present in relatively fine material with one or more free surfaces exposed to air, such cohesion cannot develop under saturation. This is the principal cause of the softening up of granular soils, as well as clays, under saturation. Hence, all tests bearing on the stability of a relatively impervious fill should be conducted on saturated material in order to determine the safety of such a structure in its critical condition.

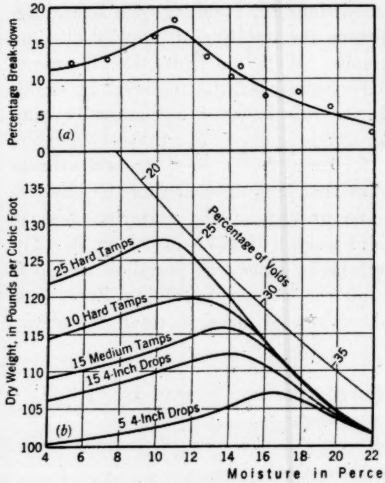

FIG. 11.—COMPARISON OF EFFECT OF MOISTURE CONTENT ON COMPACTION AND ON BREAKDOWN.

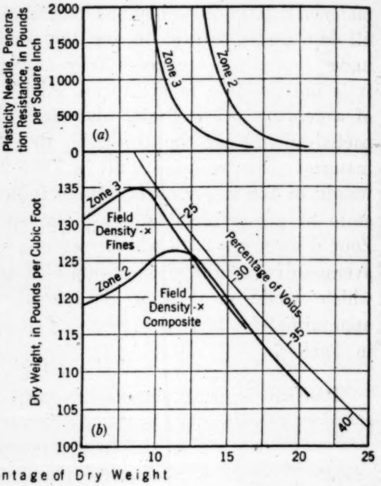

FIG. 12.—SOIL CHARACTERISTICS.

The author does not mention the penetration needle in connection with soil analysis and gives no reason for this omission. Based on tests (as yet incomplete) conducted at the laboratory at San Gabriel Dam No. 1, it is believed that the significance of the penetration or plasticity needle has been misinterpreted in the past. These tests tend to show that the penetration needle, although an excellent moisture indicator on the wet side of the peak of compaction (see Fig. 12) is not reliable as an indicator of stability of a fill if the pore water is under stress.

The safety of a dam fill composed of insoluble material depends directly on the shearing strength of its grain structure as long as over-topping is prevented. The shearing strength for a given density, in turn, depends on the rate of percolation and the pore-water stress. Although the rate of percolation primarily depends on the grain size, the pore-water stress depends on the condition of loading and particularly the rate at which load is being applied. Hence, the influence of the sudden application of load on a saturated dam fill, due to earthquake, for example, is an important part of the analysis of safety.

William C. Hill,[18] Assoc. M. Am. Soc. C. E. (by letter).—Engineers concerned with highway construction and soils will agree with the author that "probably the most severe test for the stability of earth material is as a wearing surface for an earth road." During the last few years a wearing course of sand and gravel stabilized with a binder soil has been developed for low-cost, dustless, road surfaces and bases for bituminous mats.

In Minnesota, the gravel to be stabilized in this manner is mixed with binder soils ranging from a sandy loam to a clay with plasticity indexes from 18 to 45. Care is taken that the grading of this mixture falls within the limits of a narrow band developed through the efforts of the soils engineers of the Highway Department from observations on a large number of existing gravel roads.

These roads were examined to determine their surface performance under varying traffic and climatic conditions. Samples were taken and analyzed in the laboratory to determine the gradation of those mixtures which were yielding most satisfactory performance. On the basis of these results, together with subsequent observation on some of the earlier projects stabilized by the Maintenance Department, the present specification was developed. This band differs from that of the United States Bureau of Public Roads given by the author, as shown in Table 8. (In a later report[19] than that cited by the author,[9] the Bureau has discontinued the use of the No. 270 sieve in favor of the No. 200, for practical purposes).

TABLE 8.—Percentage Passing by Weight

Sieve	U. S. Bureau of Public Roads grading	Minnesota grading
1-in.	100	....
¾-in.	85 -100	100
⅝-in.	....	95 -100
⅜-in.	....	70 - 95
No. 4	55 - 85	....
No. 10	40 - 65	35 - 65
No. 40	25 - 50	20 - 40
No. 100	....	15 - 30
No. 270	10 - 25	10 - 20

Fig. 13 shows the relation of the Minnesota band to the theoretical Talbot curve obtained by use of Equation (1) with the exponent, *n*, equal to 0.33. This curve indicates the theoretical grading to give maximum densities for aggregates having a maximum size of 1 in. to 2 in. It will be noted that the Talbot curve falls along the middle of the band. Where a close control of the mixing of the gravel with the binder soil has kept the grading near the middle of the band, a hard dense road surface has resulted.

The author points out that there is an optimum moisture content for maximum density. C. A. Hogentogler, Assoc. M. Am. Soc. C. E., has shown[20] that temperature influences this optimum point. In a series of experiments Mr. Hogentogler used three fine-grained soils and demonstrated that the higher the temperature the greater would be the density with the lower moisture content and equal compaction. He follows this with a demonstration proving that the stability of soils varies inversely with the temperature and is a reversible action.

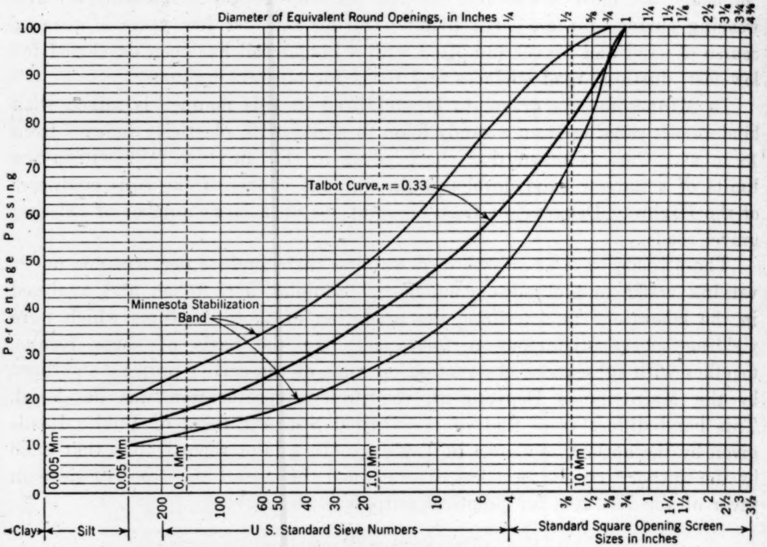

FIG. 13.—MECHANICAL ANALYSIS

A. FLORIS,[21] ESQ. (by letter).—In this scholarly paper the author discusses earth testing as an aid to the selection of materials for rolled-fill earth dams and establishes five principal requirements regarding suitability of material for this type of dams; Stability, water-tightness, workability, insolubility, and reasonable cost.

The first of these requirements is essentially one of statics and, according to the author, can be secured in a well-graded material through mechanical compaction. In other words, the author, in line with other authorities on the design and construction of earth dams, believes that the stability of a rolled-fill earth dam can be best assured, if a properly graded material is used. By analogy one might eventually conclude, that the safety of concrete dams can be taken for granted if the material is properly prepared. This is not correct, of course, because in addition to the quality of the concrete the forces acting on the dam must be investigated. This holds equally true for the earth dams treated by the author. Under the action of water pressure and dead weight, concrete dams can be analyzed quite satisfactorily. No such analysis is generally available for earth dams, and, unfortunately, the scope of the paper does not embrace this phase of the subject.

---

[21] Dipl.-Ing., Los Angeles, Calif.

Too much emphasis has been laid upon the material and very little attention, if any, has been paid to the statical condition caused by the forces acting upon earth-fill dams. As far as the writer is aware the first attempt to remedy this unfavorable condition was made by S. Ehrenberg[22], whose analysis is based upon new concepts of soil mechanics.

FRED D. PYLE,[23] M. AM. SOC. C. E. (by letter).—In discussing the factors to be considered in examining materials for the construction of rolled-fill dams, Mr. Lee has performed a notable service to engineers. Personal observations made many years ago of priming of canal banks constructed by teams, indicated that where material is reasonably well graded no trouble is encountered, but where it is of uniform size (whether clay, sand, gravel, or rock) there is a leakage with resultant sloughing on the outside of the bank where the materials are sufficiently fine to prevent free drainage. Except for the top 2 or 3 ft, satisfactory highway fills may be constructed of ungraded materials, sand, gravel, or rock, provided there is sufficient compaction, drainage, and lateral support to prevent excessive settlement.

It would appear that the following factors, in addition to those discussed by Mr. Lee, might well be considered:

(*a*) Consolidation by weight, which may be determined by testing and which will become evident in the completed dam by the rate and amount of settlement;

(*b*) Allowable percentages of colloidal and clay materials; and

(*c*) Capacity of materials, when placed in rolled-fill dams, to adjust themselves to settlement without cracking or formation of planes of lessened resistance to percolation of water.

Referring to Factor (*a*), consolidation tests should include, in addition to tests of normal material, tests of such material with the introduction of water after a consolidation head equal to one-third the height of the dam is reached. The weight load of the fill tends to increase density with corresponding reductions in the voids, and permeability. More information should be secured by engineers on the rate and amount of settlement of all dams constructed of earth and rock, both during and after construction.

An excess of fine materials (see Factor (*b*)) often means a large capacity for water which may result in excessive cracking and checking on loss of moisture content and excessive settlement.

Concise, brief definitions of certain words or terms used by the author and by others would be of assistance to those interested in studying dams constructed of earth, whether by rolled or hydraulic methods.

In order that comparisons may be made quickly with a minimum of effort it is believed advisable that gradation graphs be in millimeters, with inches and sieve sizes shown at the top and the classifications—clay, silt, sand, gravel, etc.—shown across the middle of the sheet. It is interesting to note that material having diameters between 0.04 in. and 0.2 in. is classified as gravel on gradation graphs.

[22] "Grundlagen der Berechnung von Staudaemmen," von S. Ehrenberg, *Wasserkraft und Wasserwirtschaft*, 1929 No. 23.

[23] Hydr. Engr., City of San Diego, San Diego, Calif.

As it is practically impossible, in the construction of rolled-fill dams, to mix materials from several sources to secure a modified material having or approaching the ideal characteristics, it becomes necessary to determine the suitability of local materials by inspection and by applying the laboratory tests, suggested by Mr. Lee.

Under the heading, "Impermeability", the author discusses permeability coefficients without mention of the degree of pressure or loading on the materials when tested. As the pressure has an effect on the voids, there must be some effect on the permeability coefficient.

JOEL B. COX,[24] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a greatly needed contribution to the literature on earth dams. Especially to be commended is the clear statement of the requirements of earth suitable for rolled-fill earth dams. The discussion of these requirements is, of necessity, unequal in its satisfaction. The study of grading is an important contribution to current knowledge of the subject, but it must be emphasized that the close relationship between porosity and grading shown by Fig. 1 is obtained from a single series of soils from a comparatively uniform source. The importance of this will be recognized on comparing such an example of Hawaiian laterite as Sample No. 233-*B* in Table 9 which gives a porosity, with the most careful packing, of 64.8 per cent. Its grading curve plotted on Fig. 1 certainly does not indicate the grading as a cause of the high porosity. This porosity is due to the peculiar expanded character of the fine colloidal material in all such soils.

Mechanical analysis cannot be expected to shed much light on this and similar conditions, largely because, by present methods, it is restricted to particle sizes of 0.005 mm and larger.

The excellent treatment of compaction would be improved by a critical discussion of the permissible air content at maximum compaction, which, according to the writer's observation, is a most important quality of suitable soils for rolled-fill construction.

The relationship between permeability and permanence and satisfaction of an earth-filled dam is discussed in this paper insufficiently. The effect of permeability is twofold: (1) The economic loss due to leakage from the reservoir; and (2) the effect on the dam itself. The latter is dependent largely on the relationship between the finest fraction of the soil in the dam and the velocity of percolating water. A far higher permeability is safe with a soil composed of sand and gravel than one containing silt and clay.

The author's main proposal that mechanical analysis be used as a preliminary basis for the selection of material, must be carefully covered by reservations, as Mr. Lee does. There is an intimate relationship, of course, between porosity and permeability and the mechanical composition of the material. In any soil containing an appreciable proportion of material finer than 0.005 mm, however, the qualities of the soil are so governed by the finer, colloidal fraction in its composition that mechanical analysis is of little value in interpreting or estimating the observed data. Since permeability and porosity are measured with an ease entirely comparable to that of making accurate mechanical analyses, it is not clear why there is an advantage in using the indirect and remote measurement rather than the direct one as a basis for selection. Table 9 and Fig. 14 give mechanical composition data, porosity, and permeability for a selected group of seven typical samples of Hawaiian soils, which illustrate the difficulties of using mechanical analysis in comparing materials of unlike origin. The low degree of compaction possible with such soils, the high air content, and the extraordinary elasticity under rolling which makes compaction in an earth dam exceedingly difficult, the impermeability which prevents proper drainage of the down-stream face, and the ease with which the finer fraction is removed by any percolating water, all render these soils extremely hazardous in rolled-fill dam construction, even if some of them fall within the mechanical analysis limits proposed as satisfactory. The lack of relationship between mechanical analysis and permeability is shown not only by these samples, but by such a sample as *L*15–*S*10 of Table 5, the permeability of which is not more than 0.0001th as much as would be estimated from its grading curve in comparison with the others shown.

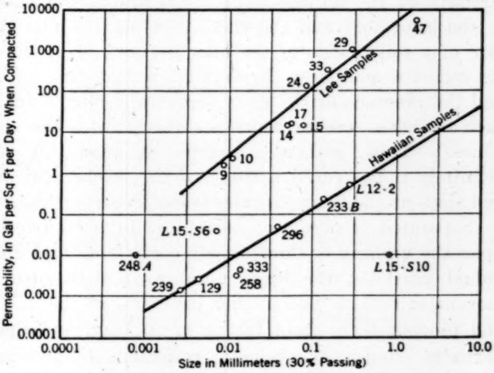

FIG. 14.—RELATIONS BETWEEN PERMEABILITY AND PARTICLE SIZE

Fig. 14 shows graphically the enormous difference between soils of entirely different character but with somewhat similar mechanical analysis curves. The fact that the two average lines representing the Lee samples and the

Hawaiian samples differ by ratios of from 1 000 or 10 000 to 1 in permeability clearly indicates the danger of too great dependence on such data. It is true that Mr. Lee points out that grading is more important than particle size in governing permeability, but no satisfactory measurement of different degrees of grading appears as yet available. The writer believes that although a mechanical analysis may be developed into a useful tool, furnishing criteria for estimating relative differences between soils of a homogeneous series, it will always be necessary to fall back on direct measurements of permeability, porosity, and compaction in comparing widely different soils.

Mr. Lee's experience with a siltstone soil and his recognition of the undesirability of adobe and lateritic soils for rolled-fill dams is important to the engineer engaged in such work. It is to be hoped that the discussion of this paper will bring forth a practicable proposal for a measurement of the workability of various soils.

STANLEY M. DORE,[25] M. AM. SOC. C. E. (by letter).—The use of soil laboratory results as aids in determining the suitability of materials for the construction of earth dams is well descrbed in this paper. The stability of an earth embankment depends primarily upon the shearing strength of the materials of which that embankment is built and, as the author points out, high shearing strength in soils exists when there is a proper combination of cohesion and internal friction. Whether or not the cohesion is due to the strength of the minute films of water (as the author contends) many tests in the laboratory and elsewhere bear out the fact that the larger the proportion of a soil that is of the finer grained, or of the clay, size, the greater are its cohesive qualities. Especially in materials of a glacial origin, cohesion and the presence of the finer particles go "hand in hand", and the value that such cohesion reaches depends directly upon the sizes and quantity of these "fines." Thus, without a sample at hand, the cohesion of a material is definitely indicated by a study of the mechanical analysis curve, the number and sizes of the finer particles being shown on the curve.

Separated from the cohesion, the internal friction of a material depends upon the grading or "uniformity coefficient" and upon the shapes of the individual particles, the large number of sizes furnishing more resistance to movement because the smaller particles fill the voids between the larger ones and prevent them from tilting or rocking, and the sharp, angular, cut-clear particles offering much more resistance to movement than rounded, worn, smooth particles. An examination of the mechanical analysis curve would indicate the extent of the grading, and microscopic examinations would reveal the predominating shapes; and from these examinations the internal friction of a material is indicated Mechanical analysis curves that are concaved upward show graded material of relatively higher shearing strengths, and curves that are convex upward show ungraded materials of lower shearing strengths. Thus, from the mechanical analysis curves and the microscopic examinations, both factors of the shearing strength can be estimated—namely, the cohesion and the internal friction—and the judgment of the degree of stability of a given material based upon visual examination and "feel" to the hand can be augmented considerably by these estimates.

---

[25] Associate Civ. Engr., Massachusetts Metropolitan Dist. Water Supply Comm., Boston, Mass.

The shearing strength of a material is increased by compaction. Vibration is the most important factor in securing satisfactory compaction and density, and the author has not directly mentioned vibration as a means for securing compaction. The success of tamping, rolling, or compacting by other mechanical means usually depends to some extent upon the vibration attending these operations, and because of its great value in obtaining high degrees of density and compaction, various types of mechanical vibration equipment are supplanting, and will supplant, many of the "pressing or loading" types of compacting machinery now (1936) in use.

Without doubt, the best materials for use in rolled impervious embankments are those which are well graded and which contain fractions of all sizes from pebbles to clay; but the engineer must not lose sight of the fact that rolled fills, satisfactory for the purposes intended, can be built of certain uniform or ungraded materials and that it is often a question of economics whether the more, or the less, preferred materials are used.

In Fig. 4 the compaction curves for loam seem to give the highest densities. Such loams must be well graded, must contain appreciable quantities of pebbly or gravelly materials, and must be consolidated by heavy equipment in order to obtain such high densities. If these loams had contained large quantities of ungraded silts and sand in addition to a small percentage (say, 5%), of organic materials, such high densities would not have been obtained. When compacted in 6-in. layers, with a 5-ton, 40-in., sheepsfoot roller, top soils have dry weights generally within the limits defined by the stipled area in Fig. 15. These values cannot be plotted as a single curve, due to the effect of the variable organic content of the different top soils used on the critical

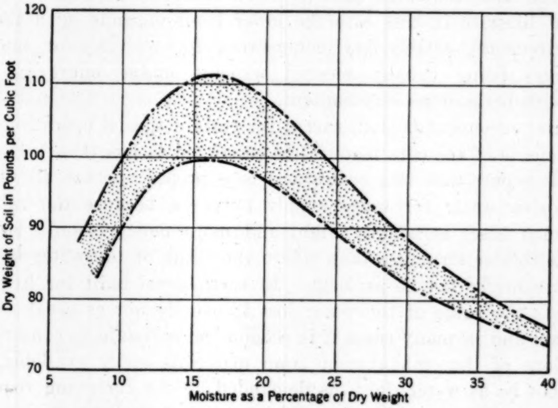

Fig. 15.—Foundations Top-Soils for Impervious Refills, Quabbin Dams

moisture content needed for maximum limits. The limiting curves in Fig. 15 show the general average conditions that yield best results. For instance, in Fig. 15 is indicated the moisture-content, density-compaction curves of loams consisting of a mixture of top soils and subsoils. The organic content in these materials averages 2 to 5% and the diagram shows that with very satisfactory compaction the densities were not greater than about 110 lb per cu ft.

The recommendation of the author for the upper limit of the clay fraction in materials for use in compacted fills is well chosen. Materials that have a clay fraction of about 30 to 35% can be compacted only with considerable difficulty because they cannot be worked satisfactorily due to the fact that in material of this nature enough of the "superfine" and colloidal particles are present to make the mass "sticky", "jelly-like", and resilient. However, the lower limit is not quite so definite. Materials containing little or no clay can be compacted satisfactorily, provided they are otherwise suitable and that the quantity of the clay fraction necessary is really dependent upon the impermeability requirements and not upon the ease or difficulty with which such material compacts. Of course, the compaction is somewhat easier when a small percentage of clay is present because, when moist, this clay lubricates the mass somewhat; but with sufficiently heavy equipment and the proper moisture contents, materials with little or no clay can be compacted satisfactorily and without undue difficulty or expense. For uniform or ungraded materials Mr. Lee indicates that a lower limit of perhaps 15% may be needed; but likewise in this case the lower limit depends upon the permeability requirements, satisfactory compaction for stability of materials of glacial origin being usually secured without undue effort in ungraded materials with little or no clay content.

The writer recommends that, except for certain special conditions, permeability coefficients of the core material be restricted to less than 1 gal per sq ft per day. It seems that this restriction is a proper one for all dams to be used in storing water for water supply purposes, because the value of the water in such cases is usually high, and more money should be spent in obtaining a tighter structure than where the value of the water lost through the structure might not be as large. In earth dams built for hydro-electric developments the value of the water lost is usually not as great as in water supply dams; and in many cases it is economical and safe to construct impervious portions of the embankment from materials easily available, although they may not be as water-tight, as demanded by the foregoing requirements. In such cases the permeability coefficient could exceed 2 gal or even 3 gal per sq ft per day; and the stability of the structure, if proper drainage of the down-stream section of the dam were provided, would not be endangered.

The author's proposal to use the mechanical analysis curves in choosing the limits for suitable materials and, arbitrarily, to establish such limits for graded and ungraded materials, is a good one. However, in the curve limits suggested, the parts representing these limits are not useful above the 40 or 50% size, and the most important parts are those between the 0 and 30% size.

Fig. 16 shows the Kendorco[26] classification in reference to the limits established by the author. In this classification, the words, "uniform" and "variable", are used in the same manner that the author uses "ungraded" and "graded." The finer of Classes 6 and 7 and all of Classes 8 and 9 represent materials suitable for impervious sections of the rolled-fill dams in accordance with the author's limitations. Classes 2, 3, 4, and 5, and possibly the coarser of Classes 6 and 7, represent materials that are probably unsuitable, although the curves for them fall outside the prescribed limits only at the smaller sizes. Thus, it seems that the important part of the curve for material of glacial origin is in the vicinity of the 5 to 10% sizes only, and the location of the limits elsewhere is immaterial. Although the limits chosen by the author will be satisfactory in nearly all cases, they must not be used too rigidly as it is very probable that materials perfectly suitable for the pur-

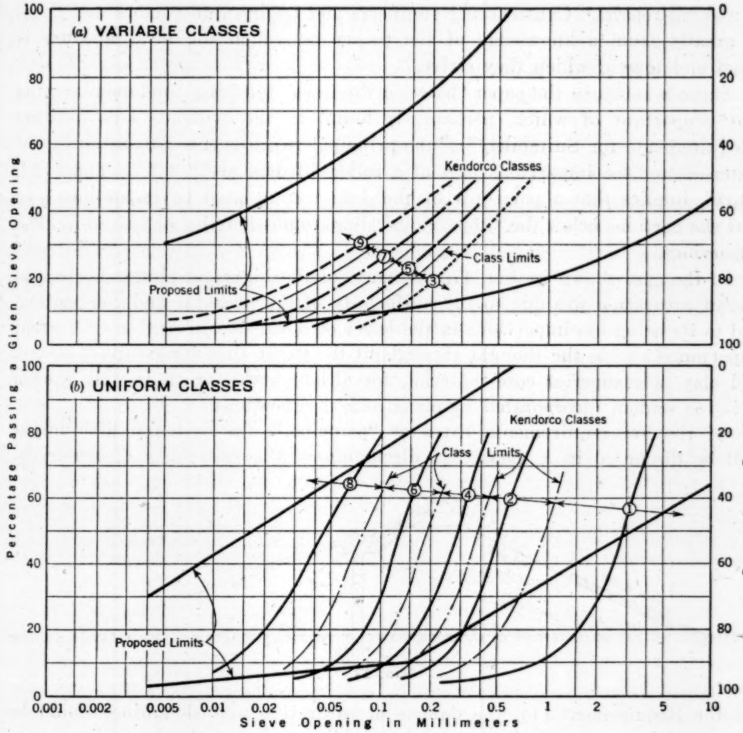

FIG. 16.—IMPERVIOUS SECTIONS OF ROLLED-FILL DAMS: COMPARISON OF PROPOSED LIMITS IN MECHANICAL ANALYSIS WITH GRADED AND UNGRADED MATERIALS OF GLACIAL ORIGIN.

---

[26] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 689–690.

poses intended will be found, which, in some individual cases, will have mechanical analysis curves that will lie outside of one of the limits shown for a short distance.

John E. Field,[27] M. Am. Soc. C. E. (by letter).—Engineers will welcome a technical treatment of the selection of materials for the more impervious parts of an earth dam, as a guide to design and construction of hydraulic and rolled-fill structures, and in masonry and rock-fill dams, where the necessity of blanketing portions of the reservoir basin sometimes arises, particularly in making repairs. Constructing engineers and engineer inspectors will benefit greatly from a knowledge of the theory on which the ideal mixture is based and toward which they strive.

There is much in the paper "between the lines" touching fundamentals, the most important of which, perhaps, is found in the sentence (see heading "Requirements for Suitability"), "the principal requirements for suitability of materials for the impervious part of a rolled-fill dam are * * *." The word, "part", implies that a part only of the dam section need be impervious and that the portions below the "impervious" diaphragms may be, or should be, less impervious.

In the case shown in Fig. 17, the cause of the high and almost horizontal line of saturation was due to the uniformity of the material and compaction, and to its being too impervious in the lower or down-stream section. Of great importance also is the thought throughout the paper that a mixture of gravel and clay is a superior core material, for although this truth is well known, it is too seldom incorporated in plans and specifications.

Of the five requirements listed as "principal", the first and fifth might well be discarded in a theoretical discussion of the suitability of materials.

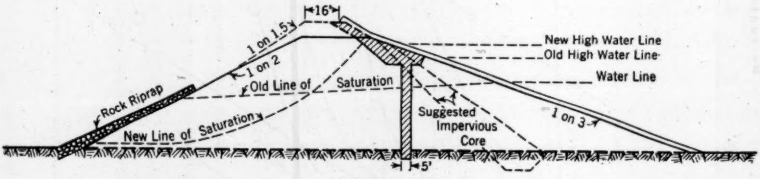

Fig. 17

As for Requirement (1), the danger of saturation and sloughing should be prevented by proper drainage and by rigidly confining the impervious core. Cost (see Requirement (5)) should not be considered in arriving at an ideal; it should be considered only in the practical application to a specific problem after the ideal, toward which it is desirable to strive, has been fixed.

The ideal mixture, local materials considered, and the methods of attaining it, has use in many structures other than dams and where the quantities involved are small, although unit costs may be high as, for example, back-fill around culverts and siphons under large canals, the lining of canals passing over cavernous limestone or through very porous sections, and the back-filling of trenches in abutments and cut-off trenches of earth-fill dams.

---

[27] Cons. Engr., Denver, Colo.

The use of a nearly ideal mixture at considerable unit cost is shown in Fig. 17, a case in which the writer repaired an earth-fill dam. The dam, then about ten years old, had threatened to slough on the lower slope whenever the water rose to within 10 ft of the high-water line, and heavy riprap had been placed on the lower slope to enable the owner to use one-half the reservoir's capacity. The material in the fill was almost wholly of disintegrated granite containing some loam, clay, mica, and sand. It is unnecessary to give the details of the work, except to state that the mixture was 33% clay, with a small mixture of sand and loam, and 67% of the disintegrated granite excavated from the dam. The moisture content was about 10%, giving a stiff product easily handled and tamped; the width of the vertical trench was only 5 ft.

The repairs were successful in stopping all tendency to slough, the lower slope dried up and after five years' use no weakness has appeared. The cost was amply repaid by the gain in capacity above the old, theoretical, high-water line, the increased depth being about 7 ft. Notable are the very thin "impervious" vertical diaphragm, the more porous material back of it, and the change in the line of saturation.

With impermeability secured in a diaphragm, it is not always required that it have hardness, permanence, or stability. In the Necaxa Dam, and in many others of the hydraulic-fill type, the cores are probably of a consistency that would permit a lead weight to sink through their entire depth, but such a condition requires that the fluid core be firmly confined.

In all dams, weight is required to oppose the horizontal water pressures, and a high line of saturation and upward pressures decrease the effective weight. An impervious diaphragm and adequate drainage below it are effective and practical in lowering the line of saturation, and with these provided, the compaction of the body of the dam merely adds some weight and a more rigid support to the core, but adds nothing to its impermeability.

Therefore, it appears that a light diaphragm, made as impervious as possible with the ideal mixtures of sand, gravel, and clay, is more to be desired than a thicker section with an approximation to the ideal. Mechanical mixers of large capacity can be built and, in the writer's opinion, will be used in the not distant future to furnish the ideal material for the diaphragm, and at that time the formula and practice which the paper seeks to develop, will be used.

In his "Synopsis", the author mentions "the traditional manner of determining suitability of material" and intimates its inferiority to scientific methods; but the use of scientific methods and the blind adoption of methods and formulas are equally dangerous, particularly if the cost is considered.

The late James Dix Schuyler, M. Am. Soc. C. E., states[28] that he had seen more mistakes in the ordinary earth-fill dam than in all other engineering structures coming under his observation. In this statement the writer heartily concurs, but wishes to add that the most numerous and serious mistakes he has observed in earth dams have been made by engineers of high technical attainments, particularly in the matter of cost, where the engineer failed to appreciate and take advantage of local conditions and materials, but adhered to theoretical formulas.

---

[28] "Earth Dams", by James Dix Schuyler.

There is one desirable quality in fills of mixed clay and gravel not mentioned by the author, namely, that shrinkage cracks are lessened or obviated. In flood-control reservoirs, particularly in the arid regions, the dams may stand for years, become thoroughly dried out, and shrinkage cracks become a menace when floods fill the reservoir.

Referring to the use of tools and clogging (see heading "Workability"), the writer feels that the disk harrow is a valuable tool in securing uniformity of mixture and of moisture; that the mere stirring of the fill material gives opportunity for the smaller particles to find and fill the voids much more certainly than even the sheepsfoot roller; and that thorough mixing by the harrow obviates the danger of clogging the rollers and other tools.

Movement seems to be essential to thorough compacting and the moisture content should give sufficient fluidity to the material for it to move under the roller. A slight wave just ahead of the wheels of heavily loaded trucks, or a shallow rut pressed into the surface of the fill, indicates that the material is sufficiently fluid, whereas deep ruts indicate too much moisture and no ruts at all indicate too little.

Insolubility.—The writer has found as high as 24% of soluble matter in soils and in the case of one dam that failed he found, by the use of distilled water as a solvent, 8%, and by the addition of 1% of hydrochloric acid, 15%, of soluble matter. In every case, especially in the arid regions, solubility should be one of the first considerations and a knowledge of the geologic source of the material should be ascertained.

Neither clay nor adobe is essential to impermeability. Glacial flour or the slimes from stamp-mills are quite as impermeable and are of greater stability and higher frictional resistance. A search for, and recognition of, these materials and their use should be kept in mind in all glacial-deposit and mining regions.

In practice, the engineer first determines the ideal mixture of clay, gravel, and water. In construction, the percentage varies from time to time in spite of the most careful supervision and willing co-operation, and the author (see heading "Stability: Grading") advances the same idea: "In earth-stabilization practice * * * natural materials must be used, which conform as nearly as possible to an ideal grading."

Through "traditional" methods, the engineer-inspector and his assistants must be able to recognize material variations instantly and to apply the corrective measures at once, without waiting, for sampling and the results of laboratory tests; and eternal vigilance, and immediate corrective action is the price that must be paid for good work and proper progress. For quick inspection, the writer has found the use of the compression needle valuable, especially in impressing the dump boss and foreman with the idea that a covered-up fault would certainly be detected.

In the paragraph that introduces Table 2 is found mention of specifications "requiring exclusion of adobe soils." What is locally known as "adobe soil" varies widely in different localities, and a definition covering all varieties would probably be "a soil from which sun-dried brick can be made." It often contains considerable loam (another term extremely indefinite), and sand. In specifications, the writer would probably state that "adobe mixed with sand and gravel shall be used in the impervious core section", and add that "shales and indurated materials, although partly decomposed, shall not be used."

William P. Creager,[29] M. Am. Soc. C. E. (by letter).—In the writer's opinion, the author has done very well with the limited available data. He has advanced a step farther toward the establishment of definite limits beyond which it would be inadvisable to go in the use of soils for rolled dam construction; but, as he states, his hope is that his criteria will bring forth additional data from which may be evolved a basis for preliminary selection.

It is significant that his hope does not extend beyond criteria for a "preliminary" selection of materials. In this, he has shown himself conversant with the fact that many characteristics of soils, such as grain shape and grain composition, are not indicated by mechanical analysis but that they have much influence on the behavior of the material. Thus, at best, only a rough approximation of the essential characteristics of materials can be obtained from mechanical analyses.

His comparisons of mechanical analysis curves with stability are especially pertinent. Recognizing the well-known fact that the greatest density and, hence, greatest stability, results from a well graded mixture, he has shown in Fig. 1 the shape which curves of well and poorly graded mixtures assume on the usual chart of mechanical analysis. Fig. 1, together with his comparison of mechanical analysis with compaction curves, Figs. 3 and 4, brings out vividly that the best materials not only must be well graded either coarse or fine particles being less suitable.

Thus, in Fig. 4, the "fine sand" (Sample *L*1-1) has no very fine particles and hence is lacking in cohesion. Therefore, it possesses insufficient compressibility and squeezing properties to expel the entrained air effectively. It has low density and many air voids. Next above in Fig. 4 is the "sandy gravel" (Sample *L*15-*S*10), which contains a small percentage of fines. This is a fairly well graded mixture and hence has high density. However, it has insufficient fines for the proper compressibility and squeezing effect to expel a large part of its entrained air.

Closest to the curve of zero air voids are the loams, shown by full lines in Fig. 4. These loams are the ideal materials containing between 16% and 33% of clay accompanied by abundant coarse particles. They have the fewest air voids.

Finally, the silty clays and clays, Samples *L*15-*CG*, *L*11-1, and *L*-8*A*, have a large percentage of fines, providing excellent squeezing properties; but they possess such low permeability that little if any draining of water and air can take place. Hence, they are of low density and have many air voids. It is difficult to account for the fact that Sample *L*11-1 shows up better than Sample *L*-8*A*. This is one of the inconsistencies that creep into the best of tests.

---

[29] Cons. Engr., Buffalo, N. Y.

The writer feels that Fig. 6, defining proposed limits for graded materials is a great help in preliminary studies, provided: (1) That its use is tempered with experience and judgment; (2) that it is remembered that some materials outside these limits might be used; and (3) that some materials within such limits may be entirely unsuitable. Sample 42, for instance, lies wholly within the limiting curves, yet it has a compacted porosity of as much as 44.4%, and is quite permeable. This material is eliminated under the author's somewhat indefinite specification: "* * * it is not sufficient that the mechanical analysis curve should lie between the respective coarse and fine limiting curves; it must also have a shape corresponding to, or approaching, that of the limiting curves."

In order to assist in a graphical indication of this specification and more nearly define reasonable requirements, the writer suggests the possibility of using an additional curve, *AB*, Fig. 18, which would be the fine limiting curve for all materials having less than 15% clay content; that is, the curve for material having less than 15% clay content must not cross Curve *AB*. Thus, Sample 42, having less than 15% clay, lies wholly within the author's limiting lines, but it crosses the fine limiting line, *AB*, and, therefore, is undesirable, whereas Sample *L*15-*S*9 is on the order between good and bad material.

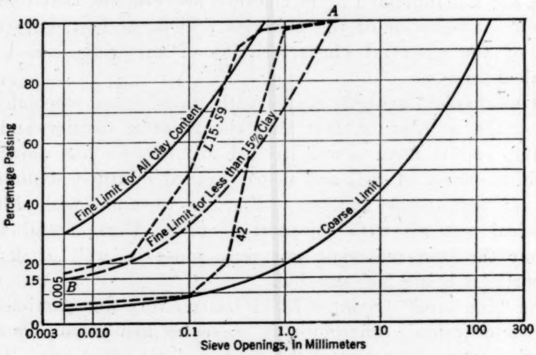

FIG. 18

It is not claimed that this additional curve will supplant judgment, but it is just one more step to assist in visualizing requirements. The writer's suggestion is not confined to one additional curve. Other fine limiting curves might be used for materials having less than, say, 22% and 8% clay content.

In conclusion, the writer can see no practical need for Fig. 7 showing proposed limits for ungraded materials. Comparing the coarse limiting curves of Figs. 6 and 7 for graded and ungraded materials, any material having a curve which lies outside the ungraded limiting curve, but inside the graded limiting curve, automatically departs from the ungraded class, and Fig. 6 would apply. Referring to the corresponding fine limiting curves for graded and ungraded materials, it is the writer's belief that the difference between these curves is far less than is justified by present knowledge of the relation between suitability and mechanical analysis.

JOSEPH JACOBS,[30] M. AM. SOC. C. E. (by letter).—(1) The demand and need for a material expansion of water storage facilities throughout the United States, the economic importance of safety for the heavy investments involved in potential developments, and the fact that much of the required new storage will be effected by means of earth dams, renders this paper of timely interest.

(2) The earth dam is the oldest type known to Man. Where truly adapted to the site it is probably the best and most permanent type and, in fact, there are now existent more dams of that type than of all others combined. Despite these facts there is yet much to be learned concerning earth dam construction: How to select and effect the most economic mixture of available materials, the best degree and best methods of compaction, the stability of section, economic slopes, core-walls, and the best location and depth of cut-off walls, the density and permeability of various mixtures of earth materials, etc. It is mainly within the past decade that intensive study has been given to the problems of soil mechanics, the formulation of their basic principles, and the application of these principles to practical engineering. The entire realm of earth dam construction is still a fair field for research and this research should include not only detailed laboratory investigations, but also an intensive study of existing dams in respect of the aforementioned elements.

(3) In this connection it is of interest to contrast the densities that have been attained in compacted earth mixtures with those of concrete mixtures. In compiling certain data from engineering literature on earth dams, the writer finds that of about thirty actual tests of earth mixtures, for which mechanical analyses were given, the dry weight of the mixtures, after compaction, ranged from 96.7 to 132.5 lb, and averaged 115.4 lb per cu ft, or only 67.8% of the like weight of the constituent material. He also estimated, for each of these thirty tests, the theoretical maximum density that would obtain if all particles of the mix were placed so as to effect maximum density—that is, if the voids in each size of material were filled successively with smaller sized materials as far as these were available. This estimate indicated that the densities of the actual mixtures ranged from 71 to 96%, and averaged 82%, of their respective theoretical maximum densities. These latter, depending on the particular proportions of the mix, ranged from 120 to 165 lb, and averaged 141 lb per cu ft, or about 83% of the weight of an equal solid of the constituent material.

(4) The foregoing results compare rather unfavorably with those obtained in concrete mixtures. In good, modern concrete, densities of from 155 to 157 lb per cu ft are readily obtainable if desired. Of this weight, about 6% is water, thus indicating, for the mixture, a dry weight of about 147 lb per cu ft, which is to be compared with the average of about 115 lb per cu ft for com-

---

[30] Cons. Engr., Seattle, Wash.

pacted earth embankments. Other comparative figures are: A voids content of only 13.5% for the concrete mixture as against 32.2% for the earth mixture; and a 6% moisture content for the former as against two to three times that proportion for the latter. It should be noted, too, that this modern concrete is compacted not by rolling or tamping processes but only by vibration.

(5) It may be contended that an earth embankment and mass concrete are two entirely different things and that they are, therefore, not directly comparable. However, in the initial condition of the mix, and in respect of density, a comparison may not be unfair for they are both composed of exactly the same types of materials, namely, earth and rock, the cement content of the one merely replacing a portion of the silt and clay content of the other. They differ only in their relative degrees of synthetic proportioning and mixing and in method of compaction, with a final result that one attains a density which on the average is one-fourth greater than the other. The contrast is striking and, at least, suggests the query as to whether engineers are now securing the maximum economic densities in earth mixtures and as to what may be the economic limits of proportioning, mixing, and compacting mixtures for earth dam construction. The legitimacy of this query will be appreciated when it is realized how materially seepage is reduced by an increase in the density of the earth mixture.

(6) Of the many considerations to be kept in mind in the selection of borrow-pit materials for earth dam construction, and in determining their proper mix proportions, particularly for the impervious part of the dam, it is believed that the following are among the more important:

(*a*) That the material shall be of sufficient weight, and shall be sufficiently graded as to particle sizes, to ensure a high density upon compaction, and thus to afford stability to the dam structure without imposing the necessity of extremely flat embankment slopes. Safe dams can be built of relatively light materials, but the heavier material is a desideratum in order that the expense involved in providing the extremely flat slopes, otherwise required, may be avoided.

(*b*) That the material shall afford a sufficient gradation of particle sizes, and particularly that there be a sufficient proportion of fines, to ensure against percolation velocities that might cause such erosion and piping within the body of the dam as to threaten its ultimate failure.

(*c*) That the material shall afford a sufficient gradation of particle sizes, the same as Item (*b*), but to ensure against a seepage volume deemed prohibitive from considerations of economic water value alone, independent of possible physical damage to the dam by reason of such seepage.

(7) Assuming a satisfactory foundation, the stability of the dam proper, against imposed loads and attacking forces, depends mainly upon density of the embankment material in place; upon the position and gradient of the plane of saturation within the body of the dam and the volume of dam submergence below that plane; upon frictional resistance to displacement; and upon the cross-sectional form of the dam. The desired safety factor for sta-

bility, and the slopes and cross-section required therefor, are determinable from the other factors named. Most failures of earth dams have resulted either from their being overtopped by water, due to a lack of adequate spillway capacity, or to super-saturation followed by sloughing and progressive undermining toward the center from the outer slope or down-stream toe. There are few if any cases of earth dam failures that have been attributed directly to sliding. Such a failure, however, is conceivable. Under a condition of maximum loading as to water level above the dam, when maximum saturation obtains, the coefficient of friction of the embankment material is at a minimum, and, at such times, unless the base of the dam is adequately broad, a sliding movement would be possible as an incipient disturbance—and if sliding once began, disruption, subsidence, overtopping, and final failure would be likely to follow.

(8) Unless the embankment material is of reasonably good weight and grading, and well compacted, so that the plane of saturation is thereby well depressed toward the base of the dam, a condition obtains that makes for high porosity, high permeability, a high plane of saturation, a lowered resistance to movement under maximum load, and the necessity for flatter slopes and a broader base than otherwise would be required. This is due not only to the lesser basic density of the embankment and the greater volume of submerged material that loses weight by buoyancy, but also to the fact that a lesser coefficient of friction obtains under these conditions. This is illustrated in Table 10, which shows the required ratios, $\frac{\text{base width}}{\text{height of dam}}$, for the single consideration of stability against sliding. Other considerations may, and in many cases will, require base widths different from those indicated.

TABLE 10.—Ratio, $\frac{\text{Base Width}}{\text{Height of Dam}}$, for Stability Against Sliding

Weight of embankment material in place after compaction and under full water load, in pounds	Height of Dam, in Feet:							
	50		100		200		300	
	Coefficient of Friction							
(1)	0.25 (2)	0.50 (3)	0.25 (4)	0.50 (5)	0.25 (6)	0.50 (7)	0.25 (8)	0.50 (9)
120	4.9	2.4	5.1	2.5	5.2	2.6	5.2	2.6
100	6.3	3.0	6.5	3.2	6.6	3.3	6.6	3.3
80	8.7	4.2	9.0	4.4	9.0	4.5	9.2	4.5

(9) The assumptions upon which the data in Table 10 were developed, were as follows: A stability factor of two against sliding; dam heights ranging from 50 to 300 ft; a top width of 25 ft; a down-stream slope (horizontal ÷ vertical) two-thirds that of the up-stream slope; a mean weight of embankment material, above and below the plane of saturation, ranging from 80 to 120 lb per cu ft; and a coefficient of friction ranging from 0.25 to 0.50. Although greater unit cohesion and shear strengths than are indicated by these friction coefficient values are quite possible for dense, well com-

pacted materials, it is believed that, for conservative design, values of less than 0.50, and probably not to exceed 0.25, should generally be assumed. It will be noted from Table 10 how materially the required base width increases with a decrease in value of the coefficient of friction and a decrease in the density of the embankment material. Regardless of the showing of Table 10, however, or of stability computations in general, the writer would not favor earth dam slopes steeper than 1 on 2, nor base width ratios of less than 4.2 to 1, except possibly for very low dams.

(10) In this connection it is of interest to note the early British practice in India where so many excellent earth dams have been built. In 1910, Mr. A. Hill, Chief Engineer, Irrigation, presented data concerning some of these dams in a report entitled "Saturation of High Embankments of Storage Tanks in the Bombay Presidency." Although this report (which dealt with twelve dams from 31 to 81 ft in height) unfortunately contained no detailed data as to the density and mechanical analyses of the embankment materials, it did indicate that they were of average good quality, and it also contained detailed data as to embankment slopes and planes of saturation. From this report, the writer deduced the information contained in Table 11. There were some short sections of embankment slope much steeper and some much flatter than the averages shown in Table 11. Some were as steep as 1 on 1 (near the top) and some as flat as 1 on 14 (near the bottom). Furthermore, there were some short sections of saturation slopes as steep as 1 on 0.5 and as flat as 1 on 60.

TABLE 11.—DATA CONCERNING TWELVE EARTH DAMS IN INDIA

Item No.	Ratios	AVERAGES FOR INDIVIDUAL DAMS		Mean for all dams
		Maximum	Minimum	
1	$\frac{\text{Base width}}{\text{Height of dam}}$	6.7	4.9	5.70
2	Up-stream slope	3.6	2.5	3.04
3	Down-stream slope	3.9	2.1	2.52
4	Plane of saturation	7.6	1.9	3.6

(11) The author suggests that the qualitative desirability of materials for earth dam construction, both as to permeability and as to density, after compaction, may be judged by determining, from mechanical analyses of the materials, their value of *n* in the Talbot formula (Equation (1)). As to permeability, the writer questions the validity of this criterion, but believes that it is a fairly dependable index of potential density. Assuming a maximum particle size of 6 in. (152.4 mm), and a uniform value of *n* throughout for any particular mix, as the Talbot formula provides, the writer determined the theoretical proportions of the various particle sizes for that mix. He also considered a series of arbitrary mixes wherein the value of *n* was variable and for these the mean value of *n* was determined for each particular mix. Probably few natural mixes have a uniform value of *n* throughout. If it were deemed important (and the writer does not so regard it), a uniform value of *n* could be attained by extensive artificial proportioning; but such

extensive proportioning might be quite infeasible economically. Generally, the engineer must utilize, to the best advantage possible, the materials immediately at hand.

(12) For each of the mixes studied a theoretical maximum density was estimated, this being on the assumption that the various sized particles all found that proper place in the mix which would effect maximum density—a condition not fully attainable in practice. As already stated in Paragraph (3), of about thirty or more definite tests of mixtures and densities, for which data were available, the actual densities ranged from 71 to 96%, and averaged 82% of the theoretical maximum density. An 80% average would seem to be quite readily attainable. The theoretical mix of a uniform value of *n*, and the arbitrary mix of an equal mean value of *n*, are found to be not entirely accordant as to resultant densities, but they seem to be sufficiently in agreement to permit adjustment to a common density curve There is less accord as to permeability.

(13) From the computed *n*-values and densities for various hypothetical mixes, and from the recorded tests of numerous actual mixes, a graph (see Fig. 19), was developed showing density variation with variation in value of *n*. Curve *A*, Fig. 19, is for the theoretical maximum densities, assuming that all particles are so disposed in the mix as to effect maximum densities; and Curve *B* is for practically attainable densities taken as 80% of the theoretical maximum. The maximum particle size, *D*, is assumed to be 6 in. (= 152.4 mm). These curves are fairly close compromise adjustments to the platted actual computations. It will be noted from Curve *B* that maximum densities obtain for *n*-values ranging from 0.30 to 0.50, the actual maxi-

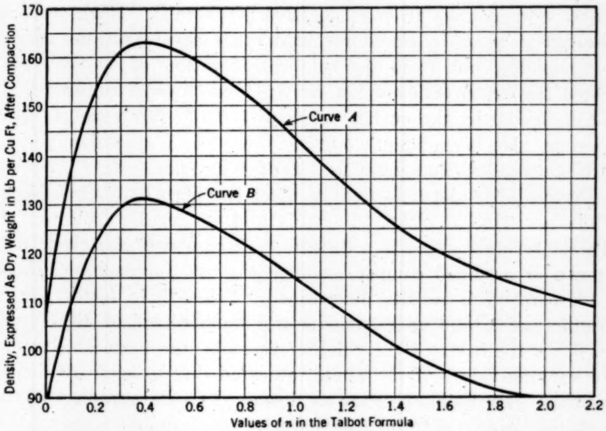

FIG. 19.—ESTIMATED DENSITIES OF EARTH MIXTURES FOR VARYING VALUES OF *n* IN THE TALBOT FORMULA (EQUATION (1)): $p = \left(\frac{d}{D}\right)^n$.

mum appearing to result for $n = 0.38$. It will be noted, too, that for densities as low as 115 lb per cu ft (which, as already indicated, is about the average now attained in actual practice) the value of n may range from 0.14 to 1.0. Although these values, both of which apply to 115 lb per cu ft, may indicate mixtures acceptable as to density, the latter also indicates a mixture entirely prohibitive as to seepage volume. Therefore, n alone, unless it is rigidly restricted within narrow limits, will not suffice as a criterion of all requirements for a good earth mixture for dam construction.

(14) The author states that a seepage loss of 0.1 gal per day per sq ft and, under certain conditions, in excess of 1.0 gal per day per sq ft, might be permissible. Ignoring the question of possible piping, and considering only the economic value of the water loss, it is not a simple matter to determine permissible seepage. It depends upon many factors: Primarily, upon the actual value of water in the particular locality and for the particular project involved, but also upon the relation of the monetary value of the annual seepage loss to the total annual cost of the project; upon its comparison with the extra cost of alternate methods of water securement that might avoid the seepage; upon whether or not the seepage water can again be utilized farther down stream, etc. Water values may range from \$500 to \$50 000 per cu ft per sec and storage costs from \$2 to \$200 per acre-ft. High seepage loss is to be avoided if possible, of course, and other considerations may make it entirely untenable, but from the sole consideration of the economic value of the water, the writer believes that seepage losses several hundred-fold greater than that indicated by the author (perhaps 500 to 1 000 times as great) may be permissible. He is confident, too, that there are many entirely stable earth dams with seepage losses as great as 5 gal per day per sq ft.

(15) Permeability depends mainly upon the porosity and "effective size" of the dam material in place. For mixtures of regular grading, according to the Talbot formula, there is a definite "effective size" for every value of n. From known or assumed compaction densities, as, for example, those shown in Fig. 19, porosity is readily determined. From these factors, an assumed water gradient of 1, and an assumed water temperature of 60° F, the writer determined, on the basis of the Slichter formula, the permeability of various mixes for varying values of n. These indicated that to keep within the maximum limits of permissible seepage as discussed in Paragraph (14) the value of n should not exceed 0.4 and the "effective size" should not exceed 0.5 mm. It also indicated, for the seepage limit designated by the author, an n-value of 0.26 and an "effective size" of only 0.025 mm.

(16) Such computations, however, can at best be accepted only as rough guides. In the first place, mixtures of irregular grading, but of the same mean value of n, give "effective sizes" and permeabilities that differ somewhat (and, in some cases, appreciably), from those of the regular grading determined by the Talbot formula. In the second place there is much uncertainty as to the dependable accuracy of any of the present empirical formulas for ground-water movement as applied to the type of earth mixtures considered herein. It should go without saying that in actual dam construction, empirical formulas, to which have been applied the mechanical analysis factors of

the earth mixture, should not be the main reliance for permeability determinations. There should be a comprehensive program of permeability tests of the actual materials, mixed and compacted to a condition as nearly that which will obtain in the final dam, as is possible.

(17) Seepage velocities that may cause piping should be avoided, of course. Generally, piping is a slow, continuing process that leaches out particles, progressively from fine to coarse, and which, unless halted, means ultimate structural collapse. The earth mixture, therefore, should be such as will permit no seepage velocities capable of dislodging and moving out the smallest sized particles which the dam material may contain in measurable quantity. A certain percentage of fines is an essential of good earth dam construction and some of these fines may be clay particles as small as 0.0005 mm in diameter. The writer estimates that for a safety factor of two against movement of such a particle, considering weight only and ignoring friction, the limiting water-jet velocity would be 0.00545 ft per sec, and that is the desirable limit of seepage velocity if practically obtainable. However, because there is a material friction and surface tension between particles, and because the 1 on 1 gradient upon which permeability factors are based is greater than obtains in a well built dam, an appreciably greater velocity than that stated would be permissible as far as piping is concerned. The seepage volume factor, however, intrudes itself and prevents any very material increase of that velocity. For a seepage velocity of 0.00545 ft per sec, through regularly graded Talbot mixes, the writer finds a limiting n-value of about 0.4 and a limiting "effective size" of about 0.5 mm.

(18) Seepage loss is so important a factor in connection with storage problems, and in relation to dam design and construction, that, unquestionably, there is an urgent need for further research concerning the laws governing ground-water movement. Every engineer who has had contact with the problem is aware of the glaring inconsistencies that obtain in the recorded data relating to soil permeability and to ground-water movement in general. These inconsistencies are revealed not only in the comparison of actual tests with estimates based on empirical formulas, but also in a comparison of the actual tests themselves, independent of any estimates by formula. Numerous instances can be cited of great disparities in actual tests of seepage through materials practically identical as to density, porosity, and "effective size"—and even greater disparities between actual tests and formula estimates. From a number of actual permeability tests of materials for which the writer computed discharge by one of the generally accepted empirical formulas, he found disparities as shown in Table 12. The degree of accuracy of the actual tests is not known but, presumably, they were made with care and are reasonably accurate. In any event, it is clear that either the tests or the formula as applied to graded earth mixtures is grossly in error, and it is confidently believed that it is the latter.

(19) Most of the permeability formulas have been devised for a more or less uniform and a relatively fine material and were not intended, primarily, for such graded mixtures as are customary for earth dams. They seem,

particularly, to lack applicability to coarse media, giving impossibly high velocities. They may be serviceable indicators as to the relative permeabilities of different mixtures, but should be interpreted with great caution as to absolute permeability. It may be that in the tests from which these formulas have been developed adequate cognizance was not given to the factors of entry and exit head losses; there may be error in the assumption that velocity varies as the first power of the head (and the writer believes there is error in that assumption as applied to coarse media); or there may be other factors in the problem that have not yet been discovered. Wherever the difficulty may lie, however, it is evident from the great disparities in results, to which reference has already been made, that further research is badly needed. It is the writer's judgment that this research should contemplate, in addition to laboratory tests, an intensive investigation of existing dams as to density, seepage, planes of saturation, mechanical analyses of the materials of the dam, etc. Such an investigation would involve considerable expense, but it is the safest procedure for the development of dependable formulas for the permeability of earth dams.

TABLE 12.—PERMEABILITY COMPARISONS, SHOWING INCONSISTENCIES

Case	MECHANICAL ANALYSES OF MATERIALS				Ratio: $\frac{\text{Actual test discharge}}{\text{Formula discharge}}$
	Dry weight per cubic foot, in pounds	Percentage of voids	Effective size, in millimeters	Uniformity coefficient	
1	96.7	45.0	0.250	4.0	0.96
2	119.4	34.0	0.559	9.2	2.14
3	109.3	38.0	0.066	3.0	0.0405
4	119.4	34.0	0.760	14.7	0.0149
5	117.5	34.0	0.102	18.1	0.414
6	127.0	30.0	0.100	95.0	0.000284
7	123.0	29.3	0.00085	2355.	14.35
8	113.4	31.9	0.730	5.35	2.70

(20) As final comment and, in part, as résumé of what has preceded, the writer submits the following:

(*a*) To satisfy best all requirements, that is, to secure an acceptable density and to keep within permissible limits of seepage velocity and seepage volume, the earth mixtures should preferably be such as to have an *n*-value within the range, 0.25 to 0.40, and an "effective size" not to exceed 0.5 mm. On account of the better workability of the material, due to the larger percentage of fines, the lesser values of *n* are the more desirable although it means, also, a slight sacrifice of density.

(*b*) It is permissible, and often necessary, to exceed the limits indicated in Item (*a*) but the embankment design, of course, must be adapted thereto. It may mean flatter slopes, a greater provision for drainage, the need for a core-wall, or of additional cut-off walls, etc., depending upon the degree of departure from the ideal material. If, for example, the value of *n* exceeds 1, the dry weight density will fall below 115 lb per cu ft and a base width greater than five times the height of dam will be required for assured stability.

(*c*) For the limits designated in Item (*a*), the percentage of fines, namely, material of less than 0.05 mm size, will generally not exceed 15% and may be somewhat less. With the present better knowledge of mixing and compaction methods, these relatively small percentages of fines are not only permissible, but they actually give a final density exceeding that of mixtures containing larger percentages of fines. It contrasts rather sharply with the one-quarter to one-third, or more, proportion of clay formerly deemed essential.

(*d*) To what extent economic considerations will permit increased expenditure to secure greater density of embankment materials by means of more thoroughy proportioning, mixing, and compacting than is now customary, depends mainly upon the number and proximity of available borrow-pits and upon their character in respect of the amount of additional processing that may be required. The fact that additional mixing may be rather expensive, and that the denser mixture requires more borrow-pit material for the same embankment volume, tends to limit the extent to which extra processing can be economically utilized. Generally, the available materials must be taken as they are, with no more processing than results from the excavation operations in the borrow-pit and from the spreading and harrowing or disking on the dam. The simultaneous use of borrow-pits of somewhat divergent composition may permit a nearer approach to the desired mixture, without undue synthetic proportioning, than would otherwise be possible

(*e*) An intensive research as to the permeability of earth dam embankments under varying conditions is urgently needed. It is a project that should be undertaken by the Federal Government through one of its regular technical agencies.

C. H. Kadie, Jr.,[31] Jun. Am. Soc. C. E. (by letter).—Valuable information on the selection of materials suitable for earth dams is presented by Mr. Lee. The author has developed a criterion for the selection of materials which will give excellent results within the stated limits. However, these limits seem to be too narrow. The writer believes that the design of the dam is predicated upon the available material, and that a structure may be designed and built to meet all necessary requirements by using materials which fall well outside the limits presented by Mr. Lee.

The design of an earth dam and the type of construction equipment selected to build it will vary with the materials used. To establish limits of satisfactory material would be to destroy one of the most attractive features of an earth dam, its absolute flexibility. Limiting the type of earth dam under discussion to rolled fill does not materially affect the limits of usable material. Having selected a borrow-pit, it is only necessary to design the structure and specify the construction equipment in order to obtain a thoroughly satisfactory dam. The shortest haul will not necessarily result in the most economical construction. The greatest economy will be found in the least number of station yards and the absence of any unusual construction equipment.

---

[31] Asst. Engr., U. S. Bureau of Reclamation, Yuma, Ariz.

The material which will facilitate the construction of an economical earth dam lies within a small and known radius of the dam site. These materials should be investigated thoroughly for those desirable characteristics completely summarized by Mr. Lee under the heading "Requirements for Suitability". Materials much more harsh than those shown in Fig. 7 may be used by selecting a very heavy sheepsfoot roller. In fact, the coarse limit established by Mr. Lee would probably require a roller weighing more than 2 000 lb per lin ft, which is somewhat heavier than the usual design.

As shown by Mr. Lee, Talbot's general grading formula, Equation (1), is very well suited as a criterion in selecting materials. The more nearly a material conforms in mechanical analysis to the curve established by this equation, the greater will be its compacted density. This will be found especially useful in making a determination of the depth of cut for the most desirable material in a stratified borrow-pit. It must be remembered, however, that the present power shovels are seldom able to mix materials satisfactorily during excavation, from a cut that is more than 20 ft deep. It is a fairly simple matter to prepare mechanical analysis curves of composite samples to various depths. By solving for n in Equation (1) for a series of points, the actual size of the screens used is to be preferred, the curve which most nearly corresponds to some one value of n may be determined. It will be found that many materials are quite erratic in the part of the curve referring to material larger than 1 in. If the percentage of material greater than this size is small, it will have little effect on the result and may be ignored. Having selected the best depth of cut for scattered test pits, the same system may be used in choosing the best pits.

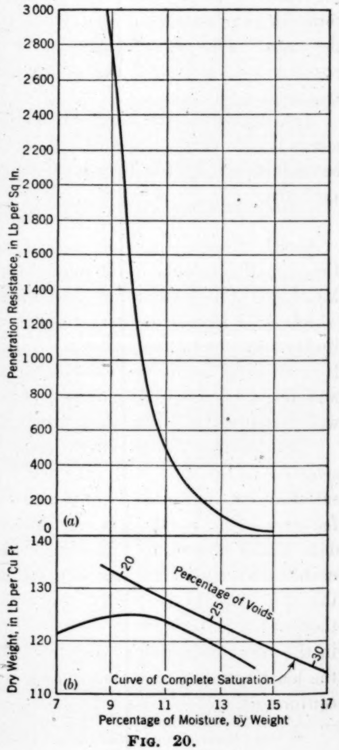

Fig. 20.

Mr. Lee has shown very clearly the known soil characteristics which may be determined by test. A knowledge of these characteristics is essential in choosing the material for a rolled-fill earth dam. One characteristic only mentioned briefly by him has proved extremely useful in the control of moisture during construction. Quoting Mr. Lee (see "Compaction"):

> "Higher water content [above critical] results in increased plasticity, larger voids, and less density, until a point

is reached at which equipment will not be supported. A lower content [below critical] may produce a fill of greater apparent stability with little or no plasticity, but one having a greater void volume and less density."

This is a relation always found in soil compaction. For any material the critical moisture is defined by the peak of the compaction curve. Fig. 20 shows a typical density-moisture (compaction) curve with a typical resistance to penetration curve (plasticity) measured in pounds per square inch. Since it is essential to obtain the correct moisture content, a knowledge of this relationship is necessary because it affords a convenient and rapid method of determining and controlling the moisture content. The details of making this test and the apparatus necessary have been presented in a series of papers by R. R. Proctor, M. Am. Soc. C. E.[32]

In the foregoing quotation the fact is mentioned that very high (above critical) moisture contents will result in a fill which will not support equipment. For satisfactory construction conditions the hauling units should not be so heavy that they will not be supported by the fill at a moisture content found to be critical for the rollers in use. Fig. 21 shows a series of compaction curves developed from the same material at various degrees of work. As the work increases (measured in blows per 2-in. compacted layer delivered by dropping a 5.5-lb rod, 18 in.) the density increases and the critical moisture content decreases. The additional work can be obtained by increased rolling or, best, by imposing additional weight on the rollers. With the present tendency toward large hauling units, and the necessity of using matched equipment (rollers and trucks), it would be best to specify a very heavy roller. This would make it possible to construct the fill at a lower moisture content and would avoid a condition of either too much moisture to support the hauling equipment, or a too little moisture content for the compaction units.

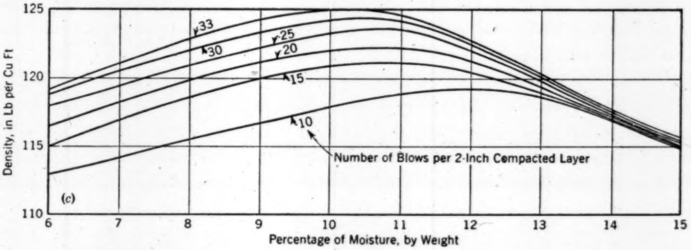

FIG. 21.—NUMBER OF BLOWS PER 2-INCH COMPACTED LAYER

RALPH BENNETT,[33] M. AM. SOC. C. E. (by letter).—In a discussion of earth dams it is usually assumed that only untreated materials are to be used. Raw fill is to be dug in convenient pits and consolidated by purely mechanical means. In other arts, there has developed a considerable use of earth which has been consolidated by the addition of imported media.

[33] Cons. Engr., Los Angeles, Calif.

For sands the use of chemicals as a binder results in a concrete for which only a limited quantity of chemical is required. The result is an impervious, hard material made in place, and without requiring the elaborate and tedious handlings of materials necessary for the making of Portland cement concrete. Although already extensively used to form underground water cut-offs and to prevent infiltration into deep excavations, there does not seem as yet to have been any chemical binder used to produce a strong and impervious face on dams, levees, or ditch banks.

For clays an extensive use of water-emulsion oil admixtures has resulted, during 1936, in the production of a water-proof material which will carry loads up to and in excess of those which the same clay, hard and dry but untreated, would carry. Clays when treated with the emulsion rolled in place, and allowed to dry out, do not again absorb moisture. They are permanently cemented by the microscopic oil film which has replaced the water film that originally held the particles. The quantity of emulsion used is determined by the extent of the fines in the raw material as the binder acts only on them. The total percentage on ordinary clays is very low and must not be exceeded, or it will lose effectiveness.

R. R. Proctor,[34] M. Am. Soc. C. E. (by letter).—Five important requirements for soils that are to be used for the construction of rolled-fill earth dams are recorded in this paper. The requirements for water-tightness and stability are of the utmost importance; the dam may fail if the soils are not sufficiently compacted to resist excessive softening or percolation that may cause erosion or piping. Mr. Lee has shown that the grading of a soil determines the minimum porosity that can be secured by use of a particular method of compaction.

The writer does not make use of grading curves, as described by Mr. Lee, because his experience has indicated that laboratory and field experiments require less time and expense, and that such results are more readily adapted to the control of construction methods.[35] This is an absolutely essential requirement for any method of soil analysis or classification; no amount of detailed laboratory investigation of soils is of much value unless there is certainty that the soils will be compacted in the dam as the engineer requires.

Until a better method is developed, the writer prefers to use the plasticity needle penetration resistance when the compacted soil is fully saturated, for a guide to stability. The results of percolation tests, first made at the minimum soil density required for stability, are used as a guide for safety from excessive percolation. It has been found that a given method of compaction may produce a soil density of 12 lb per cu ft more than that required for a saturated penetration resistance of 300 lb per sq in., whereas, in other soils, such a saturated penetration resistance cannot be secured by this method of compaction. No other explanation than variation in grading has been found; however, the writer feels that the suitability of such soils is better established by actual tests.

[34] Field Engr., Dept. of Water and Power, City of Los Angeles, Los Angeles, Calif.

[35] *Engineering News-Record*, August 31, September 7, 21, and 28, 1933.

An illustration of this fact is seen in the design of a large earth-fill dam proposed by the writer. The proposed borrow-pit was once selected for a rock quarry for a rock-fill dam. Without going into geologic details, subsequently revealed by studies of thin sections of the apparent rock under a petrographic microscope, the apparently hard and durable rock was a metamorphosed dioritic gneiss, so badly fractured that it readily broke down into an apparent soil as it was excavated and loaded into trucks. The writer had the usual compaction-plasticity curves prepared, which indicated that successful compaction of this material was possible. Several small compacted test fills were then made, using progressively heavier rollers until a roller weight and number of roller trips adequate to accomplish a soil density sufficient for a saturated penetration resistance of 300 lb per sq in. were determined.

A typical compaction curve for this material is shown in Fig. 22. Of this specimen, 43.8% was retained on a No. 4 sieve and 23% passed a No. 200 sieve. The specific gravity was 2.79. The laboratory compaction curve was prepared from the 57.2% that passed through the No. 4 screen. The extent of the field compaction was determined by measuring the density of the compacted material in place, and then calculating the density of the fines by deducting the weight and volume of all the material retained on the No. 4 screen. It will be noted that the field compaction was only 1 lb per cu ft in excess of the required minimum. This was caused by the 43.8% of rock (material retained on the No. 4 screen); other samples of similar material, but containing less rock, gave results comparable to the laboratory compaction curve. It will be noted that a compacted penetration resistance

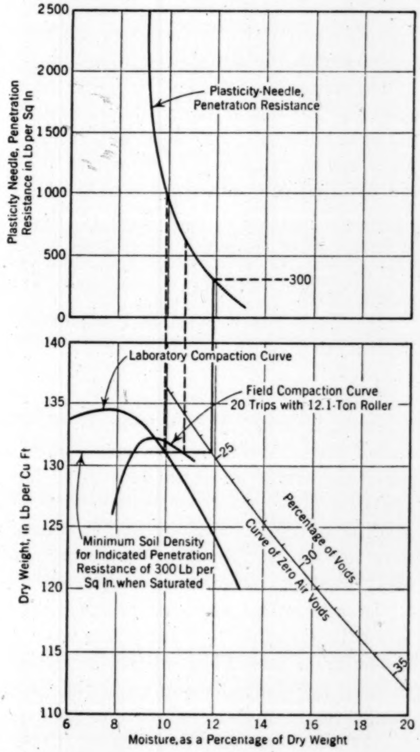

FIG. 22.

of 600 lb per sq in. represents the maximum allowable moisture content for compaction of this material; the addition of more water limits the compaction to less than the established minimum. It will also be noted that the soil can be compacted at penetration resistances greater than 2 500 lb per sq in. It is desirable to compact this soil at a compacted penetration resistance range from 2 000 to 3 000 lb per sq in., in order to reduce the cost of truck haul over the fill and to provide for consolidation during the construction period without removal of water, thus eliminating most of the slow settlement that often occurs after a dam is finished.

It is interesting to note the effect of compacting this material to a lower dry weight as, for example, that of 120 lb per cu ft. The laboratory compacted sample at this dry weight had a penetration resistance of 100 lb per sq in. as compacted, which, in the writer's opinion, is too low a value for safety in a large dam. The moisture content of this soil could increase, without change in dry weight, from 13.1% to 16.3% of the dry weight, upon saturation. The plasticity of this saturated material may be compared to that of a concrete mix of 1:2.46:2.95, dry rodded volume, with 7.1 gal of water per sack of cement. This is obviously too soft for use in a dam. This discussion clearly indicates the need for more than soil-grading curves to determine the suitability of some soils for use in earth dams.

The writer has had sufficient experience with various types of soils to appreciate the fact that the methods proposed by Mr. Lee are adequate to determine the suitability of most soils, but actual tests are needed for doubtful types Tests are also required to determine the moisture content before compaction, the required compacted dry weight of soil, and to check the results of construction operations, regardless of the degree of suitability the soils may possess. This work can be started a short time before actual construction begins, if lack of funds or other causes prohibit much preliminary experimental work.

Mr. Lee's paper required considerable effort and time to prepare, and a continuation of these efforts should be made to develop more data of this nature.

L. F. Harza,[36] M. Am. Soc. C. E. (by letter).—Much credit is due the author for crystallizing the technique of selecting ideal material for the impervious part of an earth dam in so far as this can be done by mechanical analysis. The paper is excellent with reference to the one problem of ideal grading of the impervious region, without relation to the remainder of the dam nor to its foundation nor abutments, upon the assumption that such ideal grading is consistent with other attendant facts and conditions.

In a practical application, the ideal material is seldom available in the immediate vicinity. Usually, a large part, if not all, of the dam must be built of less ideal materials in order that, for reasons of economy, it may be obtained from necessary excavations or near-by sources. One would rarely find a foundation upon which to build that would conform to the ideal grading and degree of compaction called for by the author.

---

[36] Cons. Engr. and Pres., (Harza Eng. Co.), Chicago, Ill.

Furthermore, it may be contended that the word, "stability," in the sense in which it is used when applied to a given material, is an entirely different word from "stability" when applied to the dam as a whole, which is almost synonomous with "safety"; and the two uses of the word may have little in common. The unstable core of a hydraulic fill is made stable with relation to the dam as a whole by sufficiently heavy and free draining slopes. The same principle can be applied to a rolled fill to protect the up-stream slope from damage by rapid lowering of the reservoir level. Whether or not the ideal grading should be struggled for with much consequent increase in cost depends upon the purpose of the dam, the foundation and abutment conditions, and the value of water, drainage provisions, and other factors.

It is quite natural that the author's insistence upon tightness should be emphasized in California where water conservation is of such importance, and because soluble elements are common in soils of arid regions; but a vast number of flood-control dams are likely to be built in the East where tightness beyond the requirements of safety may have no importance whatever. Obviously, it would be unnecessary to struggle for high impermeability, for example, of mere retarding dams for flood-control purposes, such as those of the Miami Conservancy District. Dams of high permeability may be just as safe and stable as very tight dams: (*a*) If the materials of different character are disposed in proper relation so that they become progressively more permeable (and amply so) toward the toe; (*b*) if each material will not filter through the next material in succession; (*c*) if the materials are not soluble; and (*d*) if ample natural drainage is provided on the filter principle to insure the escape of leakage without the carrying out of material. Each material, of course, should be compacted as much as its character permits.

It would be superfluous to struggle for the ideal grading and tightness of a dam if the foundation itself were subject to leakage, dwarfing that of the dam. This is the usual case with reference to dams in the Southern Peninsula of Michigan, some of which rest on as much as 1 500 ft of porous sand and gravel, and depend for stability upon proper drainage. Seepage is dangerous only to the extent that it is not properly handled. The art or science of draining engineering structures, especially dams, is of such importance as to deserve recognition as almost a distinct field of engineering which has received altogether too little attention.

The logical design of a dam and the selection of materials, even for the impervious part, is inseparable from its foundation and abutment conditions, drainage possibilities (whether natural or artificial), importance of water conservation, and the purpose and location of the dam. It is well to lean toward the ideal as far as consistent with these conditions.

CHARLES H. LEE,[37] M. AM. SOC. C. E. (by letter).—The generous response in discussion has fulfilled the writer's hope that the subject-matter of this paper might be expanded. All aspects of the subject have received attention, including a number of points not listed in the paper. It is regretted that the scope of the latter precluded consideration of such broader features of earth dam design and construction as were mentioned by Mr. Floris. This subject has been covered recently, however, in a very able manner by T. T. Knappen, M. Am. Soc. C. E.[16] With regard to the penetration needle mentioned in several discussions, the writer is familiar with it and considers it a very effective and useful tool.

---

[37] Cons. Hydr. Engr., San Francisco, Calif.

The five principal requirements for suitability of impervious material, as listed by the writer, were accepted with more or less amplification by all who discussed the paper. Additional requirements pertaining to shape of particles, colloidal material, and cracking characteristics have been contributed. The discussions will be commented upon in the order that the subject-matter appears in the paper.

Cohesion.—It was pointed out by Mr. Baumann that cohesion due to the surface tension of water is absent under conditions of saturation where no particle surface is exposed to air. He recommends that all stability tests on impervious fill be conducted upon saturated material. The writer confirms this rule and would add that all samples that are small enough so that the density is affected by surface tension, should be submerged when under test. This is the practice in making the Terzaghi consolidation test. It might also apply under certain conditions to shear tests.

Although open-minded with respect to the relation of thin films of water to cohesion, Mr. Dore agrees that the latter is always accompanied by the presence of "fines" and that its degree varies with the degree of fineness of particles and the percentage of "fines". In this connection, it may be stated that at all atmospheric temperatures water is present on the surface of "fines", in the form by hygroscopic moisture. Such moisture is in equilibrium with, and is derived from, water vapor in the air. Water, therefore, goes "hand in hand" with "fines", and there is the presumption that they both have some relation to cohesion.

Grading.—There is general agreement that well graded materials are ideal for the construction of the impervious sections of rolled-fill earth dams. The Talbot grading formula is also recognized as a satisfactory criterion for selection, provided n is confined to certain narrow limits. Mr. Jacobs submits statistical analyses from which he concludes that the value of n should be within the range of 0.25 to 0.40. This slightly widens the limit proposed by the writer, which was 0.25 to 0.33. As stated by Mr. Jacobs, the lesser values of n are more desirable on account of better workability of material. With the present tendency to increase the weight of rolling equipment and effectiveness of processing in compaction, however, increasing the value of the upper limit of n to 0.40 may not be inadvisable. Mr. Hill points out that the Talbot curve with $n = 0.33$ falls along the middle of the stabilization band defined by the Minnesota Highway Department for wearing surfaces for gravel roads.

Mr. Jacobs believes that the degree of conformity of a mechanical analysis curve with the Talbot grading curve within the specified limits of n is a dependable indication of potential density. Mr. Cox disagrees with this conclusion. He contributes interesting information regarding the abnormally high porosity of Hawaiian laterite soils which he attributes to the expanded character of the colloidal fraction. The condition described by Mr. Cox probably results from a high degree of flocculation in the soil induced by the chemical constituents of the local soil water. This condition is not confined to laterite soils or equatorial regions, but is encountered locally wherever soils of fine texture are highly flocculated. It may result from a variety of causes. One well known example is the soft mud deposited by fresh-water streams where discharging into salt water. Loess (wind-deposited) soils of fine texture may also have abnormally high porosity as deposited, although this may be readily reduced by heavy rolling. The latter is also true of highly porous cloudburst débris. Porous volcanic ash beds, on the other hand, may resist compaction. All such highly porous soils represent special conditions which must be taken into account, whether in dam, foundation, or other types of earth construction. The soils for which porosity and mechanical analyses were presented in Fig. 1, and also those with which Mr. Jacobs worked, are of the deflocculated type most common in earthwork in temperate zones.

Mr. Jacobs and Mr. Cox both question the value of the grading equation as an indicator of relative permeability. This subject will be discussed under the heading, "Permeability". Mr. Creager well describes the functions of the various fractions of a well graded soil mixture.

Compaction.—Mr. Jacobs compares the densities attained at present in compacted earth embankment and in mass concrete, and finds that as an average the latter attains a density 25% greater. He points out that they are composed of the same types of material and differ only in the degree of proportioning and mixing and in the method of compaction. His query as to whether maximum economic densities are being attained in earth mixtures, is a challenging one. The present tendency toward use of heavier rolling equipment, as illustrated by the work described by Mr. Baumann and referred to by Messrs. Kadie and Dore, will doubtless aid in reducing this difference. A more effective means will probably be found in the greater use of mechanical vibration equipment, as emphasized by Mr. Dore. It is also probable that, as pointed out by Mr. Pyle, there is a progressive compaction after completion of the dam resulting from the superimposed weight of material and expressed in settlement. No information is available as to the extent of such increase in density, but it is unquestionably appreciable especially in the lower courses. Mr. Pyle does well to suggest that compaction tests include loading commensurate with the weight of the dam. Mr. Hill's reference to the influence of higher temperature in producing greater density, as shown by Mr. Hogentogler's experiments, also has possibilities. This effect doubtless results from the lower viscosity of attached water resulting in increased lubrication.

Another field for investigation is the possibility of facilitating expulsion of air during the compacting process, thus reducing the air content at maximum compaction. The effectiveness of vibration in increasing density may be attributed in part to this.

Drainage.—Messrs. Knappen and Harza have contributed to this subject by emphasizing its importance in dams for flood control and other uses where impermeability is not essential. The permanence and stability of such dams depend largely upon adequate drainage. Natural drainage may be provided by use of materials that are progressively more permeable down stream. To be effective, drainage must prevent the building up of hydraulic pressure in any part of the dam to the point where the load is transferred from the solid material to water. It must also prevent the washing out of fine material. Mr. Harza does well to emphasize the importance of drainage for engineering structures.

Shape of Particles.—Messrs. Dore and Creager explain the function of individual particle shapes in providing resistance to movement in earth embankment. Sharp, angular particles develop greater internal friction than smooth, rounded ones and are distinctly advantageous. This is a characteristic to be taken advantage of, if possible.

Colloidal Fraction.—Messrs. Pyle and Cox emphasize the influence of appreciable quantities of colloidal material upon a soil in destroying the value of mechanical analysis as an index of character. Mr. Cox illustrates this phenomenon by reference to the Hawaiian laterite soils. This point is well taken and shows the value of extending mechanical analyses down at least to maximum clay size (0.005 mm) and further if possible.

Cracking Characteristics.—Messrs. Pyle and Field both refer to the undesirability of using material with an excess of fines, due to its tendency to form shrinkage cracks or planes of lessened resistance to water. Such material has a large capacity for water, and if the dam is unwatered for any length of time, cracks may form which will have disastrous effects upon refilling. This possibility is especially important in semi-arid and arid

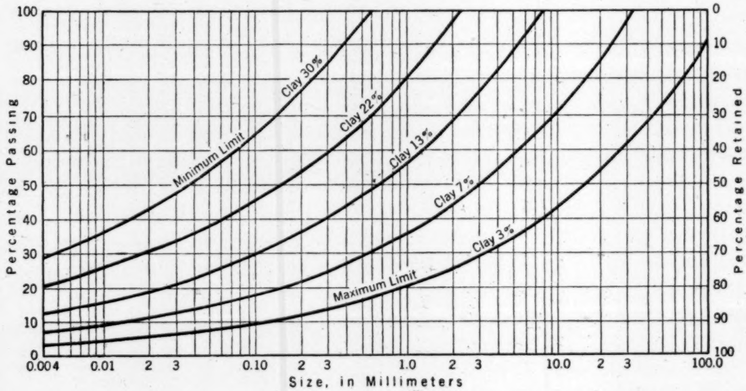

FIG. 23.—PROPOSED LIMITS IN MECHANICAL ANALYSIS FOR GRADED MATERIALS SUITABLE FOR IMPERVIOUS SECTIONS OF ROLLED-FILL DAMS (REVISED FORM OF FIG. 6).

regions. The writer's minimum limiting curve is designed to exclude such material; but if a given material approaches this limit, has an appreciable colloidal fraction, or a high degree of flocculation, it is recommended that the standard Atterberg shrinkage tests be made before final selection.

Air Content at Maximum Compaction.—From his experience with Hawaiian soils, Mr. Cox considers the establishment of a permissible air-content at maximum compaction as a very important feature of selection of suitable materials for rolled-fill dams. His need for such a limit results from the prevalence in the Islands of highly flocculated soils with appreciable colloidal fraction. In Continental United States it is believed that, except in special cases, the choice of materials in conformity with the writer's limiting curves in Fig. 23 (which is a revision of Fig. 6) will result in securing a permissible air-content. As a tentative value, the writer uses 5% by volume, or 3.5% expressed as equivalent water in terms of dry weight. (See Fig. 4 and supporting tabulations.)

Impermeability.—This subject has received discussion from a variety of experiences and viewpoints. As pointed out by Mr. Harza, water conservation is of the greatest importance in the West and minimum leakage is there essential. In the more humid Eastern States, however, water has little value, and water-tightness is not essential. This is especially true of flood-control dams, of which many have been, or are being, built.

The following is a summary of stated quantitative limits for leakage through rolled-fill earth dams:

Writer: For water-tight dams, 0.10 gal per sq ft per day is stated as a limit; the maximum allowable leakage for any dam is 1.00 gal per sq ft per day.

Knappen: A satisfactory maximum allowable limit is 100 gal per sq ft per day, the value in any given case being largely a matter of economics.

Cox: The limiting value is a question of economic loss from leakage, and the safety of the structure.

Dore: For core material in water supply dams, 1 gal per sq ft per day is an acceptable limit; for hydro-electric power dams, 2 to 3 gal per sq ft per day is acceptable.

Jacobs: The limiting value is a question of the economic value of water loss and the possibility of piping. There are many entirely stable dams with seepage loss as great as 5 gal per sq ft per day. From economic value alone losses as great as 50 to 100 gal per sq ft per day, may be permissible.

Messrs. Baumann and Field describe ingenious uses of differing types of material to produce water-tightness with stability. These represent normal practices where limited material is available for impermeable construction. Where ample satisfactory material has been available, many impervious dams in the West have been built with uniform section.

Mr. Bennett refers to the use of imported media to produce water-tightness, such as chemicals, as a binder for sand and water emulsions, and oil admixtures for application to clay. The writer might add to this list the use of sodium carbonate or sodium chloride with loam soils as deflocculants to improve water-tightness of the back-fill in core trenches or core-walls. Considerable experimental work has been done and actual use of such chemicals for this purpose has been made in several instances.

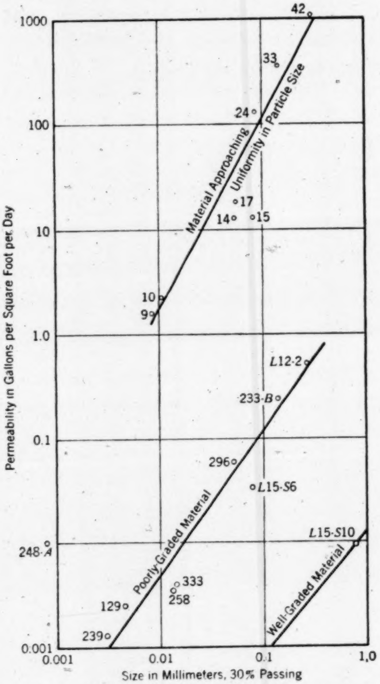

FIG. 24.—RELATIONS BETWEEN PERMEABILITY AND PARTICLE SIZE (RE-ARRANGEMENT OF FIG. 14).

Messrs. Cox and Jacobs take issue with the writer's conclusion that there is a correlation between mechanical analysis and the permeability coefficient as determined from actual test. Mr. Cox submits data for seven samples of Hawaiian soils (Table 9) and in Fig. 14 compares diagrammatically the permeability and size, in millimeters (30% passing), including in the latter study both these samples and twelve samples for which data are given by the writer (see Fig. 5). To supplement the mechanical analysis data shown in Table 9, Mr. Cox has kindly furnished the complete curves. Fig. 24 is a re-arrangement of Fig. 14, using the complete data. Examination of the mechanical analysis curves for the nineteen samples indicates the classification shown in Table 13.

With the exception of Sample Nos. 248-*A* and 258 these same groupings appear on Fig. 24 and lines designated correspondingly are shown thereon. It is apparent from this diagram that for each grading group there is a relationship between mechanical analysis and permeability and that the reason Sample No. *L*15–*S*10 has such low permeability in comparison with others is that it is the only sample having well graded material. Further-

TABLE 13.—CLASSIFICATION OF NINETEEN PERMEABILITY TEST SAMPLES

Type of material	Lee Sample Nos.	Hawaiian Sample Nos.
Uniform texture	9, 10, 14, 15, 17, 24, 33, 42	258
Poorly graded	*L*15–*S*6, *L*12–2	333, 296, 233*B*, 239, 248-*A*, 129
Well graded*	*L*15–*S*10	. . . .

* Conforming with Talbot equation for $n = 0.25$ to $n = 0.33$.

more, the diagram does not show "enormous difference between soils of entirely different character, but with somewhat similar mechanical analysis curves." It does show, however, enormous differences between dissimilar groups of soils having similar mechanical analysis curves. The differences in permeability, as shown by the grouping, are apparently due to degree of grading and not to character of soil. Within any group, the differences in permeability are due to character of soil as controlled by particle size. The eccentricity of Sample Nos. 248–*A* and 258 may be due to observational errors.

Mr. Jacobs states the writer's suggestion (which he questions) to be that the "qualitative desirability of materials for earth dam construction, * * * as to permeability * * * may be judged by determining, from mechanical analyses of the materials, their value of n in the Talbot formula." The writer's view, restated, is that materials which are shown by mechanical analysis to be graded in conformity with the Talbot equation, with values of n from 0.25 to $n = 0.33$ (curves concave upward), have much lower permeability coefficients than poorly graded materials (sloping curves straight or irregular) and very much lower than uniform textured materials (curves convex upward or vertical). This statement, it is believed, is confirmed by Fig. 24. With regard to Mr. Jacob's proposed limits of $n = 0.25$ to $n = 0.40$ and "effective size" not to exceed 0.5 mm, this condition would be fulfilled by Fig. 6 or Fig. 23 if the maximum limiting curve were drawn for $n = 0.40$ instead of $n = 0.33$. As previously stated, such a change may be desirable in the near future in view of the improvement in field compaction methods.

The writer agrees with Mr. Jacobs in questioning the accuracy of present empirical formulas for ground-water flow as applied to earth mixtures used in construction. As he well states, "permeability formulas have been devised for a more or less uniform and a relatively fine material and were not intended for such graded mixtures as are customary for earth dams." For many years the writer has depended upon actual permeability tests rather than the use of formulas.

Mechanical Analysis.—Almost every discussion included comment upon the writer's proposed limits for grading materials suitable for impervious sections of rolled-fill earth dams, as set forth in Fig. 6 and Fig. 7 and the supporting tabulations. These comments are summarized as follows:

Mr. Knappen prefaced his comments by the statement that "greatest economy generally results from the use of materials closest to the site." He considers that materials finer than the writer's minimum limit may be used for impervious core construction, dependence being placed upon the outer shell for structural strength; also that materials coarser than the maximum limit may be used where the water has little value, where large leakage is permissible, and where care is taken in design to pass the water without injury to the structure.

Mr. Baumann states that material which is not initially suitable because of gradation defects can be made so by proper compaction. The writer would point out, however, that this statement applies principally to material, the large pieces of which are readily crushed in rolling, such as that used in Zone 3 of San Gabriel Dam No. 1.

Mr. Dore considers the minimum limit satisfactory, but that curves of suitable materials especially of glacial origin, with little clay, may lie outside the maximum limit for short distances.

Mr. Creager thinks that the limits are helpful for preliminary studies provided their use is guided by experience and judgment. He believes that some materials outside the limits might be suitable and that other materials within the limits might be unsuitable. For a more accurate definition of requirements for graded materials, he suggests intermediate lower limits with varying clay content, and would eliminate entirely the diagram for ungraded materials (see Fig. 7).

Mr. Jacobs defines limiting maximum curves as those with *n* values in the Talbot equation between 0.25 and 0.40 and an effective size not to exceed 0.5 mm. The percentage of fines (0.05 mm) under these limits would generally not exceed 15 per cent. The maximum limit ($n = 0.40$) for the 5-in. maximum size of particle would slightly exceed the writer's maximum limit (see Fig. 23).

Mr. Kadie considers the limits as too narrow, believing that the design of a dam should be predicated upon the available material. Mr. Proctor states that he does not use limits, placing dependence upon laboratory compaction and permeability tests, and plasticity needle penetration tests in the field. Mr. Harza thinks that the need for attaining the ideal grading depends upon a number of factors and that no fixed limits can be established.

The use of limiting curves as a guide in studying mechanical analysis data is thus little favored, being generally confined to those familiar with dam construction for water supply storage.

Mr. Proctor and others point out that selection on the basis of mechanical analysis is at best preliminary and that other considerations, including the results of compaction and permeability tests, must form the basis for final selection. This is in accord with the writer's views as expressed in the paper. The principal field for selection by mechanical analysis, however, is in reconnaissance, preliminary investigation, general studies, small projects, etc., or where limited funds are available for investigation. Mechanical analysis is a widely known standard test of broad usefulness which can be performed at moderate cost by a variety of

TABLE 14.—CONTROL DATA FOR INTERMEDIATE FINE LIMITING CURVES (SEE FIG. 23)

Curve	Maximum size of particle, in millimeters	Value of *n* in the Talbot equation	Percentage of clay
Minimum limit: No. 28 sieve	0.6	0.25	30
Minimum limit: No. 8 sieve	2.36	0.25	22
Minimum limit: $\frac{5}{16}$ in.	8	0.28	13
Minimum limit: $1\frac{1}{4}$ in.	32	0.30	7
Maximum limit: 5 in.	127	0.33	3

established laboratories. For these reasons the writer believes that there is utility for a set of limiting curves, as shown in Fig. 23.

In preparing these revised curves, the suggestion of Mr. Creager has been followed. Three intermediate fine limiting curves have been drawn from the control data listed in Table 14. In using Fig. 23 it will be found that the most suitable materials are those which have mechanical analyses curves that lie entirely between adjacent pairs of curves.

With the addition of the intermediate curves in Fig. 23, the writer agrees with Mr. Creager that there is no practical need for Fig. 7, giving limits for ungraded materials, such limits being provided by the spread between the adjacent intermediate curves in Fig. 23.

INTERACTION BETWEEN RIB AND SUPERSTRUCTURE IN CONCRETE ARCH BRIDGES

By Nathan M. Newmark,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. Floris, Frank M. Baron, A. A. Eremin, Hardy Cross, and Nathan M. Newmark.

Synopsis

Certain phases of the interaction between the rib and spandrel structure of concrete arch bridges are discussed herein with a view toward relating the action of the structure to the system of classification of indeterminate structures presented in 1935 by Hardy Cross[2], M. Am. Soc. C. E.

Certain limiting cases of the arch with integral superstructure are normal and can be designed directly from the results of a preliminary analysis. Structures in which either the rib or the deck girder develop all the flexural resistance are normal. A third type of structure having normal characteristics for most cases of loading is similar to a Vierendeel truss, with rigid columns and with floor and rib of approximately equal stiffness.

Other structures are hybrid and cannot be designed for given working stresses by the traditional procedure of repeated analysis and design. However, where the columns are flexible the action of the structure can be predetermined and the stresses can be predicted and controlled within reasonable limits.

In the case of the hybrid structure, the same degree of economy and safety can generally be obtained by designing the rib to carry all the load, and by neglecting the effect of interaction on the deck, as can be obtained by taking account of interaction by the traditional procedure of repeated analysis and design.

Introduction

The usual treatment of an open-spandrel arch bridge as a rib without restraint due to the superstructure is clearly incomplete. Interaction between

---

Note.—Published in September, 1936, *Proceedings*.

[1] Research Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

[2] "The Relation of Analysis to Structural Design," Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1363.

rib and spandrel structure is inevitable as long as the parts of the structure remain continuous; but the fact that arch bridges designed by a procedure neglecting deck participation have apparently given good service, seems to indicate that interaction is relatively unimportant. However, arches so designed have been primarily "dead load" structures, carrying relatively light live loads and resisting live load flexural stresses effectively by virtue of the heavy dead load compression in the rib. In such an arch, when built of the proper shape, the greater part of the stress is as definitely determinate as for a statically determinate structure. It seems scarcely necessary to add that this type of arch bridge is entirely different in essential structural characteristics from a structure of the same shape designed to carry relatively heavy live loads, particularly when the size of the rib is reduced by shifting material from the rib to the posts and floor.

The Final Report of the Special Committee of the Society on Concrete and Reinforced Concrete Arches[3] has called attention to some phases of the significance of interaction. For example, in Section I, Article 3, Conclusion 7(*b*) suggests that live load stresses be determined considering the structure as a whole and not the rib alone, "because of the effect of the deck participation upon the stresses in the deck and columns rather than because of its effect upon the stresses in the rib"; and, again, Conclusion 9 points out that,

> "A deck without intermediate expansion points, constructed so as to act with the rib in carrying loads, reduces the magnitude of the live load moment at the springing where the deck does not increase the strength of the structure; and it increases the moment over the central portion of the span where the strengthening effect of the deck is greatest."

There seem to be two not very clearly defined and sometimes conflicting points of view in the Committee's report and elsewhere in the technical literature on the subject of interaction: (1) That interaction is a source of danger and should be avoided if possible by means of joints and hinges or by other means of articulation; and (2) that interaction presents an opportunity to effect marked economies in design by taking advantage of its favorable aspects. This latter point of view is best shown by a review of a paper[4] which states, "French engineers have shown Americans that remarkably light and efficient concrete bridges can be designed by considering the spandrel columns and floors as integral with the ribs."

Previous Investigations.—Any of a number of analytical methods may be used for the determination of stresses in an arch with superstructure. Most of them were developed primarily for trusses without diagonals and for building frames. In general, they will be found to consist of variations in either of two fundamental procedures:

(1) Maxwell's procedure in which cuts or hinges are introduced at enough points in the structure to make it statically determinate and then forces are found to produce continuity.

[4] "Integral Arch Action" by George E. Beggs, M. Am. Soc. C. E., on file in Engineering Societies Library; reviewed in *Civil Engineering*, December, 1933, p. 697.

(2) A method used by Hardy Cross,[5] similar to Ostenfeld's deformation method, in which various independent sets of joint displacements are produced and the forces involved are determined. These independent configurations are then combined in such proportions as to give the forces acting on the structure.

Several approximate analytical methods[6] have been suggested but are not generally available. Various simplifying assumptions permit a fairly rapid solution of the problem. The writer has made studies of different types of arch bridges using methods of analysis[7] that he has adapted, in order to test the validity of the simplifying assumptions that have been suggested. In general, none of the approximate solutions is applicable to a wide range of structural types. Exact methods of analysis require almost as great an expenditure of time and effort as that necessary for the completion of an accurate model analysis.

Analyses by means of models using the deformeter gage introduced by George E. Beggs[8], M. Am. Soc. C. E., and by models using the polarized light method[9] have been made. Deformeter model analyses are reported in articles describing the arch viaduct, at Ashtabula, Ohio,[10] the George Westinghouse Bridge[11], in Pittsburgh, Pa., and the Raritan River Bridge, in New Brunswick, N. J[12]. In these cases it should be noted that revision in design was not always made from the results of the analyses.

A model analysis was used to check a simplified theoretical analysis of the Grandfey Viaduct[13], in Switzerland. It is not clear from the article whether any advantage was taken of interaction in the design of the rib. From its size it would appear not. It may be noted that[14] "greater stresses are conceded for the superstructure than those for the main arches" due to the deformation of the arches resulting in a greater loading of the superstructure than that contributed by direct loading alone.

The experimental method may be summarized briefly as the determination of stresses in a prototype loaded in a manner similar to the actual structure.

The most notable examples of experiments on arches with decks have been those conducted on the Yadkin River Bridge[15] and the series of experiments[16] by W. M. Wilson, M. Am. Soc. C. E., at the University of Illinois, on concrete models. It is important to note that in these experiments cracking and disintegration of the superstructure occurred in tests to destruction, the superstructure being affected almost to the same extent as the rib, although the loading was chosen so as to produce maximum stress in the rib.

Object of Present Study.—This paper relates certain phases of the behavior of arches with integral spandrel structure to the general philosophy of design presented recently by Hardy Cross[2]. It is not concerned with methods of analyzing stresses, nor with the details of design; it develops what is believed to be a rational point of view of the problem, and presents material leading to a possible basis for design.

The variables involved in this problem are numerous. The mere compilation of data, whether from experience, experiment, or analysis, does not always assist in clarifying a problem in which the variables are so numerous and difficult to separate; but with the classification of indeterminate structures developed by Professor Cross, one has available the basis for classifying and interpreting data bearing on the subject, or on related problems concerning other types of structures.

It is necessary to supplement experimental and analytical data with information pertaining to experience. What evidence, if any, is there of overstress in the floors, columns, or ribs of arches that have been constructed? Where have cracks occurred, and in what type of structure? That is, what are the relative stiffnesses of floor, columns, and rib, and where are the expansion joints (if any) located? The writer hopes that those who have information along these lines will contribute to the discussion. He would ask a further question: Has an arch bridge actually been designed and constructed taking interaction into account, and what changes in floor, columns, or rib were thereby made possible, or became necessary?

INTERPRETATION OF STRUCTURAL ACTION

Classification of Indeterminate Structures.—In revising the design of a member in an indeterminate structure from the results of an analysis, it is necessary to know how the stress in the member will be affected by revision in its proportions, and by revision in the dimensions of other members in the structure. Professor Cross has defined qualitative types of structural action in terms of the response of the member to changes in design[2,17].

[17] *Transactions,* Am. Soc C. E., Vol. 101 (1936), p. 1395.

Briefly, the following types of action are defined, resulting either from external fixed loads or from imposed fixed deformations on the structure:

(1) Participation defines the action in which non-load-carrying or nuisance stresses are developed in a member due to very nearly fixed strains resulting from the deformation of the load-carrying members;

(2) Normal action corresponds to a very nearly fixed magnitude of the forces and moments acting on a member, and is developed when the forces acting on the member are practically independent of the size of the members in the structure; and,

(3) Hybrid action is best defined as action in a range intermediate between participation and normal action, where forces, moments, and strains are dependent on the size of the member considered, or on the proportions of other members in the structure.

It follows that, in redesigning a member found by analysis to be overstressed, participation stress can only be lessened by reducing the strain the member must undergo; for example, linear strain due to angle changes is easily reduced by decreasing the depth of the member. Normal stress can be reduced by increasing the size of the member, but hybrid stress may be either increased, decreased, or unchanged when the size of the member is increased. Where maximum stress arises from a combination of circumstances it is necessary to keep in mind the relative importance of the different factors contributing to the stress in a member in arriving at a design.

Load-Carrying and Nuisance Stress.—In considering the significance of over-stress, it is convenient to make a distinction between stresses depended upon to "carry the load" and secondary or nuisance stresses resulting from the action of the structure but having no useful function. Over-stress in normal action is serious. Over-stress due to participation is dangerous only to the extent that the ability of the member to perform its primary function is impaired. Over-stress in hybrid action may or may not be serious depending on whether the structure may "carry the load" safely in another way when the over-stress becomes large. In this connection, the significance of chance factors in the properties of the material becomes important.

The fact that the superstructure of an arch bridge is slightly overstressed is not always serious if the superstructure is not depended upon to reduce the stress in the rib. If it is possible to reduce the size of the rib of an arch bridge because of interaction, but if at the same time the superstructure must be strengthened and if the resulting structure is neither appreciably more economical nor certainly more safe than the structure as designed neglecting interaction, then the process is futile.

SOME PHASES OF INTERACTION BETWEEN RIB AND SPANDREL STRUCTURE

Results of Analyses; Moment Diagrams.—The writer has made analyses of different arch structures but, for the reasons stated previously, finds it difficult to draw empirical conclusions concerning interaction from the results of these analyses. However, some of the data obtained are of interest in showing, qualitatively, the effect of interaction, and are presented for that purpose.

One of the series of arches analyzed consisted of a set of five-panel structures having different decks, all with practically the same rib. Sketches of the structures are shown in Fig. 1. The rib is parabolic in shape with the moment of inertia varying directly as the secant of the angle of inclination with the horizontal. Several different values of moment of inertia of deck and columns were considered. In Fig. 1, all the structures are symmetrical about the center line. The dimensions denote relative distances and the relative moment of inertia is given as *I*. The structure with a high deck is shown in Fig. 1(*a*), the structure with a low deck and an infinitely stiff saddle at the crown is shown in Fig. 1(*b*), and the structure consisting of a flexible polygonal rib with a stiffening girder is shown in Fig. 1(*c*). Except for the saddle, the rib in Fig. 1(*b*) is the same as that in Fig. 1(*a*).

(*c*) FLEXIBLE RIB WITH STIFFENING GIRDER

FIG. 1.—TYPES OF ARCH STRUCTURES ANALYZED.

Consider the particular structure shown in Fig. 2(*a*) loaded with a force, *P*, and having reactions, *R*. Let *H* denote the horizontal component of the reactions, and let *V* denote the vertical components. At any vertical section through rib and deck, such as *y-y*, the sum of the horizontal components of the forces in rib and floor must equal the horizontal component of the reactions:

$$\text{Total } H = H \text{ in rib} + H \text{ in floor} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Furthermore, the sum of the vertical components of the forces in rib and floor must equal the total vertical shear, *V*, at the section:

$$\text{Total } V = V \text{ in rib} + V \text{ in floor} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Curves of *V* and *H* are shown in Fig. 2(*a*) with the numerical values of the total forces given on the diagram. The part of *V* and *H* resisted in the floor is shown by the stippled areas, and the remaining areas denote the part of *V* and *H* resisted in the rib. The change in the part of *H* resisted in the floor at the column points represents the shear in the column.

FIG. 2.—MOMENT DIAGRAMS FOR A UNIT LOAD AT POINT *C* ON RIB WITH HIGH DECK.

The total moment, M, about the centroid of the rib at the section considered is resisted by flexure in the rib, by flexure in the floor, and by the moment of the horizontal thrust in the floor about the centroid of the rib:

$$\text{Total } M = M \text{ in rib} + M \text{ in floor} + H \text{ in floor} \times (\text{distance between floor and rib}) \ldots\ldots\ldots\ldots\ldots (3)$$

The curve of total moment about the centroid of the rib is shown in Fig. 2(*a*) as the vertical ordinate between the pressure line for the loads (the heavy dot-dash line) and the axis of the rib, since the value of H is constant for the entire length of the structure. To this same scale, the shaded areas plotted on the rib, columns, and floor as bases, represent the diagrams of moment for these members, plotted on their compression side. The moment in the floor is replotted on the pressure line as a base, and is shown by the cross-hatched areas in the diagram. The remaining area of total moment in Fig. 2 is then the moment about the centroid of the rib due to horizontal thrust in the floor. The three parts of the total moment diagram show, then, the relative values of the three sources of resisting moment.

The moment diagrams for the arch with high deck of Fig 1(*a*) for a unit load at Point C is shown in Fig. 2 for relative moments of inertia of rib at crown, floor, and columns of 4, 4, and 1 (Fig. 2(*a*)), 4, 4, and infinite (Fig. 2(*b*)), 4, 4, and zero (Fig. 2(*c*)), and 4, zero, and infinite (Fig. 2(*d*)), respectively. For the structures with columns of infinite stiffness, the end columns have relative moments of inertia of 1 compared to the rib. The moment diagram for the arch with a low deck of Fig. 1(*b*) for a unit load at Point C is shown in Fig. 3 for relative moments of inertia of rib (except for the infinitely stiff saddle at the crown), floor, and columns of 4, 4, and 1, respectively.

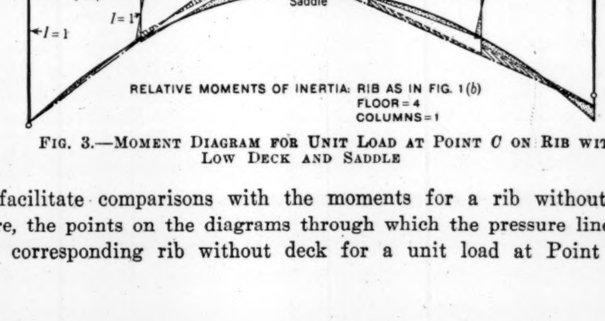

FIG. 3.—MOMENT DIAGRAM FOR UNIT LOAD AT POINT C ON RIB WITH LOW DECK AND SADDLE

To facilitate comparisons with the moments for a rib without superstructure, the points on the diagrams through which the pressure line passes for the corresponding rib without deck for a unit load at Point C, are indicated by the small circles at the springing and at the load point. The value of H for the bare rib is indicated on the diagrams.

Typical Influence Lines.—Typical influence lines for moment and flexural stress in rib and superstructure are shown in Fig. 4. They were computed for the single-span structure having a high deck without expansion joints tested by Professor Wilson, a drawing of which is shown in the Final Report of the Special Committee on Concrete and Reinforced Concrete Arches.[18]

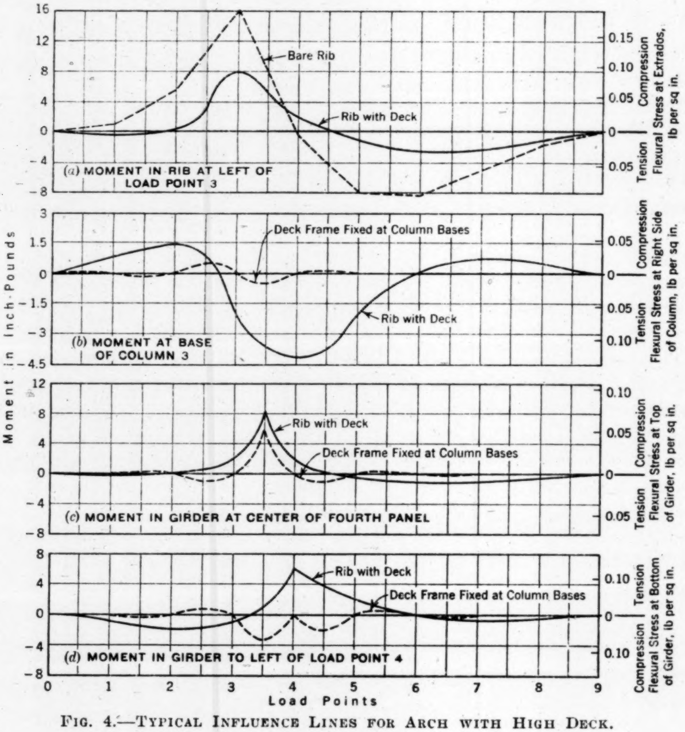

FIG. 4.—TYPICAL INFLUENCE LINES FOR ARCH WITH HIGH DECK.

The broken lines in Fig. 4(*b*), Fig. 4(*c*), and Fig. 4(*d*) show the influence lines for "primary stress" in the superstructure, defined as the stress with the deck and columns considered acting as a continuous frame fixed at the column bases. The differences between the full and broken lines in these diagrams indicate the relative effect of interaction on the moments. It is noted that the interaction effect in the floor at the end of a panel is so great that the sign of the moment for live loading is changed from that corresponding to primary action.

---

[18] *Transactions*, Am. Soc. C. E., Vol 100 (1935), p. 1486, Fig. 41(*a*).

The scales for flexural and direct stress shown in the diagrams are computed on the basis of an uncracked concrete section, neglecting the steel reinforcement. The values obtained show the relative effects of moment in the various members considered. It appears that for a single concentrated load on the structure for which the influence lines are shown in Fig. 4, the maximum live load flexural stress at the base of Column 3 is approximately 1.4 times the live load flexural stress in the rib at the same load point, when the concrete is assumed to be capable of taking tension. A comparison may also be made of the flexural stress at the base of Column 3 with the maximum stress in the corresponding bare rib at the same point due to a single concentrated load. One finds the relative values of these stresses to be 0.67 in the column to 1.0 in the rib.

Stresses Due to External Imposed Deformations.—The effects of temperature change, spread of abutments, or rotation of abutments, are qualitatively similar. As an indication of the effect of such influences on the moments in the structure, comparisons have been made for structures of the type shown

TABLE 1.—MOMENTS DUE TO A UNIT CHANGE IN SPAN FOR RIB WITH VARIOUS TYPES OF DECK (SEE FIG. 1).

(Sign of moments corresponds to a shortening of span; positive moment produces compression at top of rib and girder, and compression on left side of column.)

* Infinitely stiff saddle at crown; otherwise, rib same as bare rib.

in Fig. 1. Data are shown in Table 1 for springing reactions and moments in all members due to a unit change in span for an arch rib with various types of deck. The effect on the rib of interaction with the deck is to increase the temperature moments considerably.

Consider the deformations of an arch structure with deck due to a given change in span. If the columns have little stiffness and the floor, at all sections, has the same relative stiffness to that of the rib, the change in shape of the rib will not be altered by the superstructure. Consequently, in such a structure, the temperature flexural stress in the rib will be the same as in the bare rib. However, there will be temperature flexural stresses in the floor, which will be to the temperature stress in the rib at any section as the depth of the floor is to the depth of the rib at that section, since the deflections (and, consequently, angle changes), of the rib and floor are the same. Note that the direct temperature stresses will be higher in the composite structure than in the free rib, but the direct stresses are comparatively insignificant.

If the floor has, say, a constant moment of inertia and that of the rib varies, and the columns still have very little stiffness, the change in shape of the rib due to a given abutment movement will be altered somewhat from the change in shape of a free rib since the composite structure is relatively more stiff at the crown than at the springing compared with the free rib. Hence, there will be a greater distortion in the haunch and near the springing with a relatively higher temperature stress in the composite structure at those points than in the bare rib.

Consider now the effect of the columns. Since, in general, the columns stiffen the structure and the given displacement must take place, there will be correspondingly greater distortions in the rib with stiffer columns; and, hence, there will be greater deformation stress in rib and floor with stiffer columns. The columns also will have high moments due to deformations.

The increase in relative stiffness of the crown of the composite structure over the crown of the free rib causes a reduction in maximum live load moment at the springing, but this same cause produces inevitably an increase in temperature flexural strain at the springing. The fact that one effect cannot exist without the other is worth some emphasis.

The significance of high deformation stresses is a matter of judgment. They are almost certainly not as serious in concrete as stresses due to loads. Attempts have been made to reduce stresses due to these causes by expansion joints and other articulations in the deck of the bridge. These attempts are not always successful, sometimes merely localizing the effect, particularly in the case of expansion joints at the ends of a saddle in a low deck bridge.

It must be noted that for structures in which interaction is depended upon to reduce stresses in the rib the stresses in the deck due to deformations and temperature changes are important in so far as they tend to cause cracking of the superstructure, for cracking of the superstructure reduces its stiffness and thereby the aid which it can render the rib.

Summary of Results of Analyses.—A study of a number of influence lines and moment diagrams seems to indicate the following conclusions:

(1) The maximum live load moment at the springing line and at intermediate column points on the rib of the integral structure is considerably reduced by the interaction with the deck. For intermediate column points the reduction may be of the order of 50% when the moment of inertia of the floor is equal to that of the rib. The moment between column points in the rib is reduced considerably more than the moment at the column points if the columns are stiff.

(2) The interaction between rib and deck for live load adds to the primary moment in the floor at the center of the panel, computed as for a frame fixed at the column bases. At the ends of the panels, the interaction moment in the floor is opposite in sign to, and may be much greater than, the primary moment.

(3) The interaction live load moments in the columns are considerably greater than the primary live load moments, even for slender columns. The interaction column moments are greatly increased by making the columns stiff.

(4) Where the columns are quite stiff and the rib and floor have approximately equal moments of inertia, points of inflection or points of zero moment are close to the center of all members for most conditions of loading.

(5) Temperature and deformation strains at the springing in the rib of the integral structure are much greater than in a bare rib. Temperature strains in the deck are likely to be of the same order as those in the rib. The temperature strains are increased by making the columns stiff.

Treatment of the Arch with Superstructure as a Flitch-Beam.—If the spandrel columns of an arch bridge are quite flexible and closely spaced, it is evident that the deflections, slopes, and angular changes along the arch rib must be equal to those along the floor (except for the change in length of the columns, which effect will be neglected, but can be taken into account if necessary). Then all direct stresses due to thrust will be carried by the rib, and the relation between moments and flexural stresses in rib and floor can be predicted and controlled by varying their relative depths and moments of inertia.

In other words, the structure can be designed as if it were composed of two members placed side by side as in a flitch-beam. This concept dates back at least to Rankine,[19] and has been used apparently by Considére.[20] Professor Cross[3] has discussed several new aspects of this treatment in connection with his system of classification.

An analysis for the purpose of design may be developed along the lines of Professor Cross' treatment as follows: The deck girder will have primary stresses due to its action as a continuous beam. These stresses are due to the dead load of the deck only, and the entire live load. The arch rib will take all the thrust, most of which is due to dead load. Then the difference between the working stress and the primary girder stress is available to resist interaction flexure in the girder. The difference between the working stress and the stress due to direct thrust in the arch rib is available to resist flexure in the rib. Temperature and deformation stresses may also be discounted from the working stress.

---

[19] See "Civil Engineering," Seventh Edition, 1871, pp. 313–314; and other editions at approximately the same page numbers.

[20] See, for example, "Cours de Beton Armé," by A. Mesnager, Paris, 1921, p. 198.

The stress due to interaction flexure in the girder is to the flexural stress in the rib approximately as the depth of the girder is to the depth of the rib. The rib and deck resist the moment (except for primary moments) approximately in proportion to their moment of inertia.

A few rough figures will enable an estimate to be made as to whether a tentative combination of depths of girder and rib is efficient or inefficient, and will give some idea as to what can be done about it; for example, if the girder is found to be overstressed, it must be remembered that increasing the depth of the girder may increase interaction stress, although it decreases the primary stress.

Analyses of several structures by the writer have indicated that for loads applied at column points, the approximation involved in the assumption that the columns are closely spaced is very good. This approximation is strictly true for the particular case of a two-hinged arch rib polygonal in shape with a deck composed of straight prismatic segments between column points, in which the ratio, $\frac{(EI\ \cos\theta)_{\text{deck}}}{(EI\ \cos\theta)_{\text{rib}}}$, has the same value in every panel. For loads between column points it is necessary, for accuracy, to find, first, the column reactions, considering the floor as a continuous beam, and then to apply these reactions to the composite structure.

Where there are expansion joints in the floor the total moment must be taken by the rib. Where the floor is not continuous over the springing the moment at the springing is resisted entirely by the rib.

For certain cases it is possible that neglect of the columns will not be on the safe side. If the columns are stiff and the floor flexible there is considerable local flexure of the floor and the moments in the floor may be several times as great as those assumed on the basis of equal angle changes, unless the stiffness of rib and floor is of about the same order.

Relative Importance of Sources of Stress.—The principal sources of stress for which an arch bridge is designed are dead load, live load, and deformations such as those due to temperature change, shrinkage, abutment movements, etc.

Neglecting the effect of rib-shortening there will be no interaction stress for dead load if the pressure line for the weight of the rib and the dead load reactions of the deck acting as a continuous frame fixed at the column bases fits the arch axis. With some reservations,[21] rib-shortening may be considered as deformation stress. The manner of constructing the structure must be considered in evaluating the effect of rib-shortening; for example, if the arch centering is struck before the deck is constructed, rib-shortening due to the weight of the rib will not cause interaction stress.

The dead load and live load moments in the floor considered acting as a frame fixed at the column bases (defined as the primary moments in the floor) depend mainly on the panel length. The interaction moments in the floor are a function of the relative stiffness of floor and rib as well as of the span length of the rib. Adjustments of the depth of floor and rib, therefore, may make the interaction stress in the rib almost anything that is desired within reasonable limits. If it is desired to reduce interaction stress in the floor to a minimum, it is most easily done by reducing the depth of the floor by a proper choice of details and arrangement of framing.

For very short arches, say, spans up to 50 ft perhaps, the dead load stress is relatively small compared to the live load stress for an open spandrel arch, but such short spans are usually constructed more economically with filled spandrels. For arches of perhaps 150 ft, or more, in length, the dead load is generally more important than the live load. For long-span bridges interaction has no effect on the major part of the stress in the arch rib. In this connection it is interesting to note what has been written[11] concerning the design of the George Westinghouse Bridge of 412-ft span length:

> "A model study of the main span was made with the Beggs Deformeter to determine the stiffening effect of the superstructure. This study showed that the negative live load moment at the springing line would not exceed 60 per cent of the moment calculated for the bare rib. When this moment is reduced to terms of fiber stress the reduction is only from 780 to 730 lb. per sq. in."

A description[12] of the Raritan River Bridge, in New Brunswick, N. J., with a span length of 202 ft, contains the following comment:

> "Each of the main arch spans consists of three hingeless ribs, 12 ft wide, designed as free ribs by the application of the elastic theory without taking into account the restraining action of the superstructure. The design was checked by the use of deformeter gages on a celluloid model, and the agreement with the analytical method was practically exact. A determination of the stresses in the rib was also made on a complete model of the rib and superstructure, and marked reductions in the moments, thrusts and shears were noted due to the stiffening effect of the spandrels and floor. However, since the superstructure was poured after the centering was struck, it does not relieve the rib of any of its dead load stresses. The braced condition of the rib is applicable under live load, but as the live-load stresses comprise but a small proportion of the total, no advantage was taken of the reduced stresses in a redesign of the rib."

In even shorter arch bridges it may be noted that a decrease in live load stress in the rib is to some extent offset by an increase in deformation and temperature stress.

---

[21] "Relation of Analysis to Structural Design," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1363, especially p. 1365.

Studies made of arch bridges in Allegheny County, Pennsylvania, for both springing and crown stresses for spans between 180 ft and 400 ft, led to the following conclusions[22]:

> "For the extreme condition considered, the moment due to temperature and shrinkage was doubled to indicate the possible effect of additional moment from any cause such as a temperature drop or shrinkage greater than the assumed or movement of the supports. This investigation leads to interesting conclusions. Considering the extreme condition of combined stress, which gives an index to the ultimate safety of the rib, it develops that:
>
> "(1) The live load stress is a relatively small proportion of the total ranging from about 15 per cent for spans approximating 400 ft. to about 25 per cent for short spans. These percentages apply to shallow ribs, and are smaller for deep ribs.
>
> "(2) The arch shortening stresses may become more than 50 per cent of the total for deep ribs."

The stresses in the columns cannot be estimated very closely. The columns are ordinarily not designed for moment in any case, and usually not even for direct stress. Their least dimension depends upon their height, and when all the columns are made the same width, this dimension depends on the height of the longest column. The columns may possibly be considerably overstressed in flexure due to interaction. This is not necessarily serious unless the columns are depended upon to reduce the stress in the rib.

Various studies made by the writer seem to indicate that the column action is generally always hybrid. The effect on the column moments of increasing the size of the column, is demonstrated in Figs. 2 and 3. Moreover, even when the columns are so stiff that further increase in their section does not attract more moment to them, the column moments are still sensitive to variations in the ratio between rib and floor stiffness.

CLASSIFICATION OF ARCHES WITH INTEGRAL SPANDREL STRUCTURE

Rib with Flexible Deck.—If the superstructure is very flexible compared with the rib the interaction stresses, due to movement of the column bases, will be small compared with the primary stress in the deck, considering the column bases fixed. This type of structure is clearly normal with participation stress in the deck.

It is worth while to examine the possibility of reducing interaction stresses by detailing the superstructure so that it has a high degree of flexibility. Jack or spandrel arches and fascia beams may be omitted and the slabs framing into the floor-beams at each panel may be used to secure flexible construction. A structure so designed may possibly be overstressed in the deck, but the over-stress will not be serious since the deck is not depended upon to carry load. Any cracking in the deck will relieve the stress, but will not cause over-stress in the rib because the rib is proportioned to carry the entire load.

A method for determining interaction stresses in a structure of this kind has been suggested by Hardy Cross.[6] The method is akin to that commonly used to determine secondary stresses in bridge trusses and is as follows: For the given condition of loading determine the deflections of the column points in the arch bridge. In general, these deflections will be a horizontal and a vertical translation and a rotation. For these given deflections find the stresses in the superstructure. If the forces at the column base are small compared to the loads acting on the arch, no revision is necessary. If they are not negligible a revision may be made by computing the additional deflection of the arch rib due to these forces and revising the figures. If this revision is large, the method will not work. It may be used, however, to determine whether or not the secondary stresses are serious in any particular case.

---

[22] "The Design of Concrete Arches in Allegheny County, Pennsylvania," by G. S. Richardson, M. Am. Soc. C. E., *Proceedings*, Am. Concrete Inst., Vol. XXVII (1932), p. 650.

The flexibility of the deck depends mainly on the panel length, and it is evident that decks of the same type and panel length in structures of different length will be practically the same in stiffness. The longer the arch bridge, the stiffer will be the rib. For structures of short and moderate lengths the deck, of necessity, will be fairly stiff as compared to the rib. The flexible deck type of structure will usually be found, therefore, in long spans.

The Flitch Arch.—If it is necessary or seems desirable to make the floor fairly heavy, it is possible to make use of the flitch-beam concept in the design of the structure, and depend on the floor, but not on the columns, in interaction. Where both the rib and the floor are depended on to carry the load, the structure is hybrid, but the controlling relations are comparatively clear; the designer can "tell the structure what to do" with reasonable assurance that it will act in the way he designs it.

The particular case of a flexible flitch arch with stiffening girder is of interest. Several arches of this type have been built in Switzerland, Sweden, and Finland. The Landquart Bridge, in Switzerland, is of this type, has a polygonal rib about 10 in. deep connected by flexible columns to a floor supported by girders approximately 3 ft in depth. Stresses in this type of structure may be developed directly from the flitch-beam concept by considering a two-hinged arch rib having the shape of the given rib and a moment of inertia variation, in which $\frac{ds}{I}$ is equal to $\frac{dx}{I}$ for the girder. The analogy holds for flexural stresses due to all causes, including rib-shortening. Of course, all direct stresses are carried by the arch rib, including direct stress due to rib-shortening and deformations. The secondary flexural stresses in the rib may be obtained from the relation that the flexural stress in the rib is to the interaction flexural stress in the girder approximately as the depth of the rib is to the depth of the girder. This type of flitch arch is a normal structure with participation stresses in the rib adding to the primary stress due to thrust.

The flitch-beam concept may be applied to the structure with a saddle connecting the deck and rib, providing the columns outside the saddle are fairly flexible. The section through the saddle may be considered as having an infinite moment of inertia. It should be pointed out that stresses in such a saddle, even for given moments, shears, and thrusts, cannot be computed accurately by methods of elementary mechanics. Usually, it will not be necessary to compute the stresses since the resistance of the saddle to flexure is very high. If the deck outside the saddle is quite flexible it may be convenient to consider the section common to rib and deck as a part of the rib alone, and neglect any other effect of the deck. The method of computing the participation stress in the floor suggested in the preceding section may then be used conveniently.

The flitch-beam concept applies also to the through arch bridge having closely spaced steel hangers supporting the roadway. Where the roadway is used as a tie, the procedure with slight modifications may still be used. If the tie and the roadway have no flexural resistance the structure is what is ordinarily known as the bowstring arch, which may be analyzed conveniently by the usual methods. The secondary flexural stresses in the roadway may be approximated as shown previously for similar structures.

There is nothing in the flitch-beam concept requiring that the structure be symmetrical. Unsymmetrical arches may be treated in the same manner as symmetrical arches.

Arch with Stiff Spandrel Columns.—The structure in which the effect of the columns is important is, in general, in the hybrid class. There are certain exceptions. If the columns are quite stiff, and if the rib and floor have approximately equal moments of inertia, the structure has certain normal characteristics. The corresponding simply supported Vierendeel truss is a normal structure and can readily be designed. For the Vierendeel truss an approximate analysis preliminary to design may be made by assuming points of contraflexure in the center of all members and also that at any section the moments in rib and floor are equal. For the arch, it is necessary to take into account the fact that the supports are fixed. It is noted in this connection that the arched structure is hybrid to the same extent that a bare arch rib is hybrid for live loads.

For the general case of the structure with moderately stiff columns, where the rib and floor are quite different in stiffness, the structure is certainly hybrid. It may be possible in certain cases to choose, arbitrarily, proportions which analysis will prove to be fairly satisfactory. In general, however, no definite rules can be given for the revision of such a design from the results of an analysis; nor is the stress in such a structure known certainly, even for given dimensions, because of the effect of variations in physical properties of the different members. The hybrid structure, particularly the complicated hybrid structure of this type, may be quite sensitive to variations within itself. It may be designed, of course, by choosing to neglect the uncertain factors. In any case it must be ascertained whether the neglect of these factors is on the safe side if any advantage is to be taken of interaction in the design.

EFFECT OF EXPANSION JOINTS AND OTHER TYPES OF ARTICULATION

The articulation of the structure by means of expansion joints in the floor and hinges, rollers, and sliding joints in the columns, affects principally the columns. As far as the rib is concerned, due to articulation of the deck, the dead load stress is unaffected, the decrease in live load stress over that for the plain rib is less, and the increase in temperature stress at the springing over that for the bare rib is less, than for the structure without articulation. In the floor both the interaction live load stress and the temperature stress are decreased by articulation of the floor, but in the case of the live load stress the decrease is not appreciable several panels away from the articulation.

Live load stresses in the columns are not always decreased by expansion joints in the floor. The expansion joint tends to localize the rib deformation, and, as a consequence, the neighboring columns may suffer. Temperature stresses in the columns are probably reduced in all cases by expansion joints because of the decreased stiffness of the entire structure.

Articulating the columns rather than using expansion joints in the floor is more effective in reducing the column moments, but the details of such articulations usually become quite troublesome.

SUMMARY

The most important points to be emphasized in this paper may be summarized as follows:

(1) The net effect of interaction on the total stress for which an arch rib must be designed is normally quite small. The ordinary method of designing arch structures neglecting interaction is sound, in general, since structures so designed have apparently given good service.

(2) The significance of over-stress in the superstructure depends upon whether the deck is counted upon to assist the rib in carrying the load. It may be possible to obtain greater economy by detailing floor and columns to reduce their rigidity, and hence their interaction stress, than by designing the superstructure to assist the rib. The conclusion that the deck always strengthens the rib must not be drawn too hastily. The possibility of a load cracking the deck and destroying part of the interaction must be considered. Furthermore, stresses due to temperature and movements of foundations are high in the integral structure.

(3) Certain limiting cases of the arch with integral spandrel structure are "normal," and can be designed directly, but practically all such structures of the proportions usually built are hybrid, and cannot be designed for given working stresses by the traditional procedure of repeated analysis and design.

(4) An arch with a comparatively heavy rib and flexible columns and deck supporting relatively light live loads is a normal structure with participation stress in deck and columns added to the normal stress in these members due to their action in the continuous deck frame.

(5) Another "normal" type is the structure consisting of a flexible rib with a stiffening girder. There will be flexural participation stress in the rib, in addition to the normal stress due to the direct thrust in the rib.

(6) A third type of structure having "normal" characteristics in certain cases may be described as an arched Vierendeel truss. This structure must have quite rigid columns, and floor and rib of approximately equal stiffness. The corresponding simply supported Vierendeel truss would be normal, but fixing the supports introduces complications. In this connection, it is important to note that the fixed arch rib has hybrid characteristics for live loads.

(7) Other "normal" arch structures may be secured in various ways by the manner of construction or design involving the use of articulations and flexible sections. Such structures have well marked participation stresses at such articulations and pseudo-hinges. Of course, not all structures with hinges and joints are "normal."

(8) In special cases applying to certain other arch structures which have hybrid characteristics the controlling relations are comparatively clear. The flitch-beam concept applying to the structure with flexible columns has considerable value and leads to a definite design procedure.

(9) For the general case where the columns must be of intermediate stiffness the structure is clearly hybrid, and there seems to be no convenient way of estimating in advance whether it can act as it is assumed to act in a preliminary analysis. Use of the traditional procedure of successive analysis (usually by means of a model) and design does not appear to be very promising. Such a procedure might easily be misleading, particularly where a re-design is based on an analysis which is not repeated for the new design. It is open to question whether a better structure is obtained by such a procedure than by neglecting interaction entirely.

DISCUSSION

A. Floris,[23] Esq. (by letter).—In his broad discussion of the interaction between arch and superstructure in concrete bridges, the author fails to include the arch-barrel type, often used in practice. The rib being a special case of the barrel, it is obvious that a general theory on the subject should start from this point. The analysis is greatly facilitated by the fact that the statically indeterminate quantities of the arch barrel as well as the superstructure in space, can be divided into two independent planar groups.

In the first group, the unknowns are influenced by moments and forces acting in the longitudinal plane of symmetry, whereas, in the second group, they are functions of moments and forces acting outside this plane. The proof of this theorem which reduces the space problem into a planar one has been given by Fr. Engesser[24] and later utilized by W. Schachenmeier in the analysis of arch bridges in which the action of the superstructure is taken into account[25]. In this elaborate analysis (the first of its kind as far as the writer knows), Schachenmeier investigates the complicated structure by choosing as a base system the fixed arch rib without deck. The analysis is complete and not difficult to apply, although the numerical work (as would be reasonable to expect) is considerable.

The aim of this discussion is merely to call attention to these two important contributions pertaining to the analysis of arched bridges. It does not constitute a criticism of the author's meritorious efforts to clarify the interaction between rib and superstructure in arch bridges.

Frank M. Baron,[26] Esq. (by letter).—A contribution to engineering literature which attempts to present and use a designer's viewpoint is to be highly commended. Many readers may fail to grasp the intrinsic value of Mr. Newmark's paper. The method of attack, as applied to the problem at hand, is certainly as valuable as his conclusions. It is an approach of this kind that yields fruitful information to an engineer as to the probable action of a structure. Too much of the literature recently is being deluged with methods of analysis, and sight is being lost of every engineer's goal—that of a successful design. The interpretation of analyses and tests, and the significance of factors governing a design are usually more important than the means of obtaining the required data.

A designer usually wants two types of answers to a problem—qualitative and quantitative. A qualitative study of the probable action of a structure will generally lead to the quickest estimate of the quantities required. A quantitative study gives only a quantitative answer, and does not lead into possibilities of structural control, unless one is to carry it to limits of comparative analysis. Analysis of any kind involves some assumptions, and, as a result, judgment must be trained as to the interpretation of the resulting data. One of the greatest follies in thinking is the acceptance of analytical results without properly weighing the assumptions and the probable action of the structure involved. This is where the true worth of the author's paper is distinguished. The method of attack is applicable not only to arches, but also to any type of continuous frame.

In relating the action of an arch in terms of the classification of indeterminate structures presented in 1935 by Hardy Cross, M. Am. Soc. C. E.[3], the author has presented his viewpoints on arch action analogically. Exhaustive research was involved, as one can see that the necessary data must have been gathered through the analysis and compilation of the experiences of various engineers before any interpretation of results was possible.

In considering the significance of over-stress, the author makes a distinction between stresses depended on to "carry the load" and participation stresses. It stands to reason that participation and deformation stresses should be discounted if they do not impair a member from carrying the load, or are of localized nature. In several cases the author seems to have attached too much importance to over-stress due to participation action. Such over-stress does not necessarily mean that a structure will fail. Consider the case of over-stress in the column sections, for example. What if the over-stress due to interaction is so great that the column section should crack? The member may crack, but then the structure would not fall, as the columns would still perform their primary purpose of supporting the deck, and transmitting the deck loads to the rib. If cracking is considered as a failure, then some means of articulation may be adopted at times to prevent it.

It is true that, if the column is relied upon to help the rib, and the column should crack, it might prove disastrous to the rib; but this raises the question as to whether one would try to reduce the rib section in an attempt to obtain a more economical design due to help from participation stress. A few figures can be attached to the relative costs of the elements of the structure to show the futility of this choice[27]. In some cases, the deck is probably the only element that might justify consideration of interaction help from the columns or from the rib.

As to the matter of change in the sign of the moment at the end of the panel due to interaction effect, the author has lost sight of a point that needs further emphasis. It is the importance of dead load and live load ratio upon the consideration of this effect. Then, also, is this the stress that governs the depth or cross-section of the deck? It may be important at times only from consideration of the proper placing of steel.

The selection of the type of arch and the importance of interaction effect must also be made from the standpoint of dead load and live load ratio. A long span arch is usually a dead load structure, and may be shaped so that the pressure line follows the arch axis for dead load. Interaction would not be important in this case, as the ratio of dead load to live load is usually high. In the case of a short-span, open-spandrel arch, live load may predominate, and participation becomes a problem. It is preferable to have a high dead load ratio, and the selection of a filled spandrel arch might be the answer, provided other factors remain equal. In the medium span arch then, apparently, is where the problem of interaction must usually be decided.

---

[27] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E., p. 306.

The flitch-beam concept is outstanding in the possibilities that it affords a designer. Through its use, the engineer is able to predict the degrees of stress, but what is even more important is its adaptability to structural control. The effect of one member upon another may be studied, and a choice made as to the final structure desired. Instead of having the moment curve virtually "wag" the structure, proper selection of $\frac{\text{depth}}{\text{length}}$ ratios enables the designer to "wag" the moment curve. Structures try to do what the designer wants them to do as much as they can. Judgment, therefore, is required as to whether the structure can act as "instructed."

The writer wishes to raise the question as to what a consideration of interaction effect does to the safety factor of the entire structure. The author hints at it as applied to a column section. The importance of interaction in the members of an arch may often be determined through considerations of comparative safety factors. If interaction effect is depended upon to help the rib, then a much lower safety factor would result, and probably forbid the use of a smaller rib section. In considering participation stress in the column, the writer believes the difference in total safety factor would be so slight that a designer may easily neglect interaction. The difference involved in the deck would depend entirely upon the ratio of dead load to live load, as well as the judgment upon the discounting of participation stresses.

Concluding Remarks.—The paper is one of the few in which the arch is considered as a whole structure. Judging by the time spent in the analysis and design of the rib, many designers seem inclined to assume that this is the only part of an arch, whereas the rib usually has the smallest effect on the total cost of the structure. The paper is further enlightening upon the need of interpretation as applied to results and data obtained in the field of structures.

A. A. Eremin,[28] Assoc. M. Am. Soc. C. E. (by letter).—An interesting study of the interaction stresses in the rib and superstructure of concrete arch bridges is presented in this paper. However, for conclusive results the arch bridges shown in Fig. 1 seem to have spans that are too short. The theoretical and experimental study should be extended to arch bridges with larger spans and a greater number of panels. In practice, it is seldom that an open-spandrel arch bridge is constructed with less than ten spandrel panels.

In Item 5 of "Summary of Results of Analyses", the author refers to temperature and deformation strains instead of stresses as it seems he should have done. Apparently, temperature stresses in the deck may be of the same order as those in the arch only if the relative stiffness of rib, spandrel colums, and the spandrel girders in the arch bridge are approximately the same and the bridge can be considered as a Vierendeel arched truss.

---

[28] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

The author's statement (see heading "Treatment of the Arch with Superstructure as a Flitch-Beam") that the stresses "due to interaction flexure in the girder is to the flexural stress in the rib approximately as the depth of the girder is to the depth of the rib", needs clearer interpretation. Theoretical and experimental studies available at present are not sufficient to support it. It seems evident that the relative stiffness of the straight spandrel girders and the arched rib cannot be compared in terms of a depth ratio only, without reference to the ratio of the arch rib rise to the span length. For complete study of such interaction the analysis of stresses and a comprehensive inspection of existing arch bridges may produce much useful information.

The interaction stresses in open-spandrel arch bridges vary with: (1) The ratio of the live load to the dead load considered in the bridge; (2) the ratio of the arch rib rise to its span length; (3) the height of the spandrel columns at the crown of the arch rib; and (4) the degree of restraint imposed to avoid variations in the span of the arch.

In long-span arch bridges the live load stresses are generally small as compared with dead load stresses. Therefore, the former have a negligible effect on displacements in the spandrel girders and arch ribs. In the Plougastel (arch) Bridge, in France[29], with a span length of 611.39 ft, a rigid double-deck, reinforced concrete spandrel truss was used. However, it had only two expansion joints, 116.28 ft from the center of the span. Evidently, the effect of the live load and temperature deformations in the arch rib on the stresses in the spandrel trusses was negligible.

In arch bridges with shorter spans the ratio of live load stresses to dead load stresses in ribs is larger. Therefore, the effect on stresses in the superstructure, of displacements in the rib produced by live load and temperature stresses, is greater. Various devices have been used to reduce the participating stresses in superstructures. In the Broakpark (arch) Viaduct, at Cleveland, Ohio,[30] with a span length of 192 ft 3 in. from center to center of piers, a flexible roadway deck slab served this purpose, whereas in the Wandau Enns (arch) Bridge, in Germany,[31] with a span length of 242.06 ft, expansion joints were provided at each spandrel column.

As the span length is further decreased more difficulties are encountered in making the superstructure sufficiently flexible to accommodate a possible displacement in the rib. An interesting case of a flexible roadway deck slab, with overhanging ends cut by expansion joints, is that of the arch bridge near Donner Lake, in California.[32] This structure has a span of 110 ft, divided into eleven spandrel panels. The roadway deck is on a grade of 7% and the center line of the roadway is curved to a radius of 360 ft. Nevertheless, the slab is in excellent condition and reveals no visible cracks.

[29] *Le Genie Civil,* October, 1930, p. 317.

[30] *Engineering News-Record,* October 11, 1934, p. 467.

[31] *Beton und Eisen,* March 5, 1931, p. 73.

[32] *Engineering News-Record,* March 4, 1926, p. 357.

In concrete arch bridges of short span lengths, and with heavy railroad loading, the ratio of live load stresses to dead load stresses in the ribs is large. Therefore, it is practically impossible to make the deck slab sufficiently flexible. In such structures, rigidity is generally governed, not by the ribs but by the spandrel girders and spandrel columns. Ribs are made flexible enough to reduce the participating stresses in the connecting spandrel columns. A fine illustration of this type of bridge is the Voltschiel (arch) Bridge, near Andeer, in Switzerland,[33] in which the rigidity of the spandrel columns was increased by constructing massive abutment piers founded on rock. It is more difficult to provide sufficient rigidity in the spandrel columns in arch bridges with high abutment piers. Generally, in this case, the spandrel girders are rigidly connected to arch ribs at the crown similar to that used in the Landquart (arch) Bridge, at Klosters, Switzerland.[33] Of course, the tractive forces in this case are thrown in the arch and produce unsymmetrical stresses in the ribs. Lateral forces should be included among the principal sources of stress indicated by the author. The major lateral forces in arch bridges are generally produced by wind pressures which are negligible only in arch bridges with short spans. They cannot safely be neglected in arch bridges with large spans. The difficulty of analyzing interaction stresses when the spandrel girders are rigid, when the columns must resist combined forces in the plane of the rib, and when the structure is subjected to lateral forces, is a serious one. The stresses in the ribs can be determined more readily if the spandrel girders are broken by expansion joints. The lateral forces from the spandrel girders are then transmitted immediately to the arch ribs and the lateral stresses in the ribs can be computed by a simple method presented by the writer elsewhere.[34] In arch bridges with continuous, rigid, spandrel girders and columns, the lateral stresses are carried to the high abutment piers and this design could scarcely be considered as the most economical one.

The following tentative conclusions may be made in the light of this discussion:

(1) Open-spandrel arch bridges with spans greater than 120 ft, should be designed with a flexible roadway deck slab, or the spandrel girders should have expansion joints.

(2) Rigid spandrel girders and columns may prove the most economical for arch bridges with spans less than 120 ft. (If the structure is to be designed for railroad loading the span may be increased to 200 ft); and,

(3) If it is anticipated that foundations may settle or that elastic piers may be otherwise displaced enough to change the span length, spandrel girders and the arch rib should each have approximately the same degree of rigidity, for the most economic design. In such a case the structure will be the same as that generally called the Vierendeel arched truss.

HARDY CROSS,[35] M. AM. SOC. C. E. (by letter).—This paper is worth study by those interested in interaction of rib and deck, a phase of arch design that in recent years has attracted some attention, especially in connection with the work of the Special Committee on Concrete and Reinforced Concrete Arches.[36] The paper raises the question as to whether analysis which includes the effect of the deck structure is really worth while. The Committee recommended that such analyses be made, but failed to indicate in any way what was to be done with them. Whether they should be made certainly depends largely on the relative importance of live load, dead load, and temperature distortions as affecting the total stress. Usually the ribbed arch of concrete is chiefly a dead load structure; the live load effect has become relatively important only with modern loading. Interaction is chiefly important in short spans because live load stresses may be relatively greater and also because there is more pronounced interaction. Dead load stresses are primarily compressive; live load stresses are chiefly flexural. If the live load stress becomes important it is much more useful to ask how this flexure should be provided for than merely to analyze a design more or less arbitrarily chosen.

Assuming that an analysis is to be made, the question is, then, whether it will furnish a satisfactory guide as to what should be done to improve the design. Thus, if over-stress is indicated in the columns, the question at once arises whether it would be wiser to make the columns larger, or to make them smaller; either answer may be satisfactory in some cases. Similarly, over-stress in the deck may indicate either that the deck should be made stronger or possibly that it should be made more shallow. In general, any hope of real improvement of design will depend a great deal on whether or not the designer can foresee clearly some simple way in which a structure is to carry its load; complicated analyses, unless interpreted very judiciously, rarely lead to simple pictures of structural action. This paper does furnish some simple pictures helpful to the designer.

The paper has value in drawing attention to types of open-spandrel arches designed to resist flexure in other ways than in the rib alone. It is possible to carry all flexure in the deck, that in the rib producing participation stress; it is possible (and may sometimes be desirable) to carry the flexure partly in the deck and partly in the rib. The paper makes clear that any attempt to divide the flexure between rib and deck will depend for its success upon the relative depths. Structures designed for flexural resistance in the deck have been used on the continent of Europe; they are worth some study.

It may be worth while to analyze such structures in the hope of predicting the type of interaction that can be secured, assuming that such interaction is desirable, or it may be worth while to analyze to determine whether, for a more or less arbitrarily assumed layout, such interaction is dangerous. There does not seem to be now any satisfactory way of telling from the analysis whether the condition is really dangerous. Mere computations of stress alone do not indicate the degree of safety any more than they do when secondary stresses are included in analyzing steel trusses.

[35] Prof. of Civ. Eng., Yale Univ., New Haven, Conn.

[36] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1427.

Thus, as Mr. Newmark points out, over-stress in a column due to participating flexure does not very seriously threaten the safety of the column and does not threaten at all the safety of the arched structure as a whole.

The writer is gratified to see a paper which diverts attention from algebraic manipulation to a consideration of the objectives of such manipulation.

NATHAN M. NEWMARK,[37] ASSOC. M. AM. SOC. C. E. (by letter).—The comments and criticism offered in the discussions of the paper are appreciated. Many of the points raised are of great interest.

Attention is called by Mr. Floris to methods of analysis for the arch with superstructure. The writer purposely did not discuss at any length the matter of analytical procedures. The paper was concerned with the question of why to make analyses rather than how to make them.

Mr. Baron and Professor Cross have stated the main point, namely, that it is necessary to decide what the structure can be made to do, qualitatively, before any detailed quantitative study can profitably be undertaken.

If the rib provides all the necessary flexural resistance to live load, as is usually the case, over-stress in the deck due to participation in the action of the rib may be no more serious than over-stress due to secondary stress in steel trusses. It is certainly better in such a case to detail the structure so as to make the deck flexible, and thereby reduce the participation flexure, than to attempt blindly to analyze the stress in the deck and increase its size and stiffness to provide for indicated over-stress. Such a procedure may make matters worse unless the designer knows qualitatively what the effect of his revisions will be on the structure.

On the other hand, if the superstructure is counted on to provide flexural resistance, over-stress in the deck and columns may be serious.

In certain cases where the controlling relations are relatively clear, it is possible to foretell the action of the structure. The flitch-beam concept enables one to provide a proper division of flexural resistance between rib and deck by choice of their depths.

The writer agrees with Mr. Eremin that the structures in Fig. 1 are too short to be representative of arch bridges in general. However, the results obtained from analyses of these structures showed essentially the same characteristics as the results of analyses of nine-panel arches similar to those tested by Professor Wilson,[18] influence lines for one of which are shown in Fig. 4. With the shorter structures it was possible to study a greater number of variables. The results were not intended to be used quantitatively in any case. The results of a small number of experiments, whether analytical or laboratory tests, have little statistical value when the number of variables involved is large.

Reference to temperature and deformation strains, instead of stresses, was made purposely. A temperature change or a change in span requires a corresponding change in length of the elements of the structure, and causes a distortion of the arch rib. This distortion must take place, although it can be localized, or it can be distributed by the details of the structure. The stiffer the structure and the higher the modulus of elasticity of the material, the greater will be the stresses corresponding to the more or less fixed deformations. Referring to temperature strains instead of stresses, serves to keep this point in mind. Moreover, the temperature strain is particularly significant in any consideration of ultimate strength of the structure. When combined with high stresses due to loading, the additional strain due to temperature effects and other fixed deformations accounts for only a small increase in stress on account of the nature of the stress-strain curve for concrete.

---

[37] Research Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

It does not seem necessary to enter into a detailed presentation of the implications of the flitch-beam concept regarding the effect of relative depth on relative stress of two members so connected as to have the same deflection curve. If the floor and the rib of an arch bridge are connected by closely spaced flexible columns, it is evident that they will have the same deflection curves, and consequently the same angular changes per unit length along the horizontal. Therefore they will have unit flexural strains, and consequently flexural stresses, roughly in proportion to their depths. If the columns are flexible but not very closely spaced, the relation is still approximately true for loads at the column points. When the columns are not flexible, there may be considerable local flexure of the more flexible member, whether it be rib or floor. Obviously, a simplified approximate relation has limitations. However, that does not make it useless.

The interaction stress in the floor is that due to the deflection of the arch rib. The writer's statement: "The stress due to interaction flexure in the girder is to the flexural stress in the rib approximately as the depth of the girder is to the depth of the rib," is an attempt to interpret in a simple manner the behavior of the structure. The less stiff the columns, and the shorter the panel length, the more nearly true will the approximation be. The rise ratio of the arch is not involved in the development of this relation.

The Landquart Bridge at Klosters, Switzerland, referred to by Mr. Eremin, was mentioned in the paper as an example of the structure consisting of a flexible rib with stiffening girder supported by flexible columns. Practically all the flexural resistance in this case is centered in the floor. The arch rib is polygonal in shape and carries the dead load thrust. The rib has actually participation flexural stresses approximately one-fourth the interaction flexural stress in the floor since the depth of the rib is about 10 in. and that of the floor is about 3 ft.

Mr. Eremin has stated some of the variables on which the interaction stresses depend. One might add other variables having to deal with: (1) The sources of stress (including the dead load—live load ratio, lateral forces, shrinkage, and temperature); (2) sizes of the members; (3) shape of the structure; (4) properties of the material, and variations in properties; and (5) conditions of support. It is evident that the problem is not a simple one. For this reason, the writer attempted to develop simplified "pictures" of the action of the structure rather than to indicate how an exact analysis might be made or to report statistical results of analyses or tests. Professor Cross has indicated how such "pictures" of structural action may be useful.

ECONOMIC DIAMETER OF STEEL PENSTOCKS

By Charles Voetsch[1], M. Am. Soc. C. E., and
M. H. Fresen[2], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. R. A. Monroe, William E. Rudolph, Peter Bier, Adolpho Santos, Jr., Joseph D. Lewin, F. Knapp, Ralph W. Powell, H. K. Barrows, Robert W. Angus, and M. H. Fresen.

Synopsis

Formulas are developed in this paper for determining the economic diameter of steel penstocks for hydro-electric power plants and pumping plants based on a minimum total annual cost. The formulas developed differ from those published heretofore, in that:

(*a*) The Scobey formula for flow of water in riveted steel and analogous pipes is used;

(*b*) Factors are introduced to take care of entrance, bend, and other hydraulic losses which vary approximately as a ratio of the velocity head; and,

(*c*) A loss factor is introduced to take care of the effect of the load factor, and the shape of the load curve under which the power or pumping plant connected to the penstock operates.

The economic diameter of a penstock for a certain large power development as computed by formulas developed in this paper shows a difference of only 3.25% as compared to the diameter determined from detailed studies.

Definitions of Terms

Some writers consider the "pipe line" to be the pipe between the forebay and the surge tank, and the "penstock" to be the pipe between the surge tank and the turbines. Other writers use the term, "penstock", as applying to any pipe or pipes between intake or forebay at the dam and the turbines at the power-house of a water-power development, and "pipe line" as applying to a pipe used for other than water-power development, such as water supply.

The latter distinction between the terms, "pipe line" and "penstock", is implied herein, since the formulas are equally applicable to the pipe from forebay to surge tank, as from surge tank to turbines.

Note.—Published in November, 1936, *Proceedings*.

Notation.—The algebraic symbols used in this paper are defined where they are first introduced in the text, and are arranged for convenience of reference in the Appendix. Essentially, they conform to the American Tentative Standard Symbols for Hydraulics[3] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1929.

ANNUAL COST OF POWER LOST IN FRICTION

In 1930, Fred C. Scobey, M. Am. Soc. C. E., introduced a formula[4] for head lost in friction, h_f, per 1 000 ft of steel pipe, as follows:

$$h_f = K_s \frac{V^{1.9}}{D^{1.1}} \quad \text{.........................(1)}$$

in which K_s is a general coefficient for head lost due to friction, in feet; V = the velocity of water in the penstock, in feet per second, corresponding to Q, the rate of discharge expressed in cubic feet per second; and D = the economic inside diameter of the penstock, in feet. Substituting for V its equivalent, $\frac{Q}{A} = \frac{Q}{0.7854\ D^2}$, and simplifying, Equation (1) becomes:

$$h_{f_1} = \frac{K_s\ Q^{1.9}}{631.93\ D^{4.9}} \quad \text{.........................(2)}$$

in which h_{f_1} = the head lost, in feet, due to friction in a penstock, 1 ft long; and A = the cross-sectional area.

The annual loss of power, in kilowatt-hours, at a load factor, F, per foot of pipe, is:

$$P_{f_1} = Q\ h_{f_1} \times \frac{62.5}{550} \times e \times 0.746 \times 8\,766 \times f \quad \text{..........(3)}$$

in which e = the over-all efficiency of the plant to the point at which power is sold (in the case of a power plant), or to the point at which power is purchased (in the case of a pumping plant); and f = a loss factor, expressed as a decimal, corresponding to the load factor, F, under which a plant operates (average load ÷ maximum load). Substituting for h_{f_1} its value as expressed by Equation (2), Equation (3) becomes:

$$P_{f_1} = \frac{1.17631\ K_s\ Q^{2.9}\ e\,f}{D^{4.9}} \quad \text{..................(4)}$$

The annual cost of the lost power, therefore, may be expressed as:

$$E_{f_1} = P_{f_1}\ b = \frac{1.17631\ K_s\ Q^{2.9}\ e\,f\,b}{D^{4.9}} \quad \text{..............(5)}$$

in which E_{f_1} = the annual cost of the lost power due to friction in a penstock, 1 ft long; and b = the value of the power lost by friction and other hydraulic factors expressed in dollars per kilowatt-hour.

[4] "The Flow of Water in Riveted Steel and Analogous Pipes", by Fred C. Scobey, *Technical Bulletin No. 150*, U. S. Dept. of Agriculture, January, 1930, Equation (9), p. 10.

ANNUAL COST OF A PENSTOCK

If a penstock is operating under a head, H, an expression may be written for the thickness of the steel[5], t, as follows:

$$t = \frac{0.434\ H\ D \times 12}{2\ s_g\ e_j} \qquad (6)$$

in which s_g = the gross allowable tension in the steel penstock, in pounds per square inch; and e_j = the efficiency of the joints of the penstock, expressed as a decimal. The weight of a section, 1 ft long, W_1, in pounds, is:

$$W_1 = \frac{w\ \pi\ D\ t\ (1 + i)}{12} \qquad (7)$$

in which w = the weight of 1 cu ft of steel (= 490 lb); and i = the percentage by which the steel in the penstock is over-weight, due to laps, cover-plates, rivets, welds, etc., expressed as a decimal. Substituting Equation (6) in Equation (7) (with w = 490), and simplifying:

$$W_1 = \frac{334\ H\ D^2\ (1 + i)}{s_g\ e_j} \qquad (8)$$

The annual cost, E_{p1}, of a 1-ft length of penstock is:

$$E_{p1} = W_1\ a\ r = \frac{334\ H\ D^2\ a\ r\ (1 + i)}{s_g\ e_j} \qquad (9)$$

in which a = the unit cost of steel in the penstock, in dollars per pound; and r = the ratio of the annual fixed, operating and maintenance charges to the construction cost of the penstock.

ECONOMIC DIAMETER ANALYSES

Friction Loss and Annual Cost of Penstock Considered.—The annual cost, E_{t1}, of a 1-ft section of penstock is the sum of Equations (5) and (9). To determine the economic diameter, write out this sum and equate the first derivative with respect to D, to zero; thus,

$$\frac{dE_{t1}}{dD} = 1.17631\ K_s\ Q^{2.9}\ e\ f\ b\ (-4.9)\ D^{-5.9} + \frac{668\ H\ D\ a\ r\ (1 + i)}{s_g\ e_j} = -\frac{5.76392\ K_s\ Q^{2.9}\ e\ f\ b}{D^{5.9}} + \frac{668\ H\ D\ a\ r\ (1 + i)}{s_g\ e_j} = 0 \qquad (10)$$

Solving Equation (10) for D, and simplifying:

$$D = 0.50218 \sqrt[6.9]{\frac{K_s\ Q^{2.9}\ e\ f\ b\ s_g\ e_j}{a\ H\ r\ (1 + i)}} \qquad (11)$$

---

[5] "Water Power Engineering", by H. K. Barrows, M. Am. Soc. C. E., McGraw-Hill Book Co., 1927, p. 347.

Considering Losses Other Than Those Due to Friction.—Hydraulic losses, h_h, other than those due to friction, which vary approximately as a ratio of the velocity head corresponding to the velocity in the penstock, are defined by the relation:

$$h_h = K_T \frac{V^2}{2\,g} \dots\dots\dots\dots\dots\dots\dots\dots (12)$$

in which K_T = the sum of all constants for hydraulic losses, or,

$$K_T = k_b \sqrt{\frac{\Delta}{90}} + K_e + K_t \dots\dots\dots\dots\dots\dots (13)$$

in which K_e is a constant ruled by entrance losses; K_t is a constant to take care of all other hydraulic losses that vary as a ratio of the velocity head; k_b is a constant expressing the additional head lost due to the introduction of a bend in an otherwise straight penstock (usual approximate value = 0.25); $K_b = k_b \sqrt{\frac{\Delta}{90}}$; and, Δ = the angle of bend, in degrees.

When a bend is introduced in an otherwise straight penstock, the head lost, h_b, is expressed by:

$$h_b = k_b \sqrt{\frac{\Delta}{90}} \times \frac{V^2}{2\,g} = K_b \frac{V^2}{2\,g} \dots\dots\dots\dots (14)$$

If there is more than one bend in the pipe line under consideration, K_b will be the total of the values for all bends. The loss, h_e, at the entrance to a penstock is usually expressed as:

$$h_e = K_e \frac{V^2}{2\,g} \dots\dots\dots\dots\dots\dots\dots\dots (15)$$

Assuming a penstock of uniform diameter, with $V = \frac{Q}{A} = \frac{Q}{0.7854\,D^2}$, the head loss (Equation (12)) will be:

$$h_h = K_T \frac{V^2}{2\,g} = \frac{K_T\,Q^2}{2\,(0.7854)^2\,g\,D^4} \dots\dots\dots\dots (16)$$

Substituting Equation (16) in Equation (3), P_h for P_{f_1}, and simplifying, the annual power loss, in kilowatt-hours, at the load factor, F, due to hydraulic factors, will be approximately:

$$P_h = \frac{18.70719\ K_T\,Q^3\,e\,f}{D^4} \dots\dots\dots\dots\dots (17)$$

and, consequently, the annual cost of power loss, E_h, due to hydraulic factors other than friction (compare Equation (5)) will be:

$$E_h = P_h\,b = \frac{18.70719\ K_T\,Q^3\,e\,f\,b}{D^4} \dots\dots\dots\dots (18)$$

Considering Friction Loss, Other Hydraulic Losses, and Annual Cost of Penstock.—For this case it will be necessary to determine all hydraulic losses.

including those due to friction, and the annual cost, E_p, of the entire penstock of length, L, in feet. The annual cost of the friction loss per foot of penstock is expressed by Equation (5). Let the length of penstock used for computing friction loss be L_f, and the annual cost of friction loss in the entire line will be:

$$E_f = E_{f_1} L_f = \frac{1.17631 \, K_s \, Q^{2.9} \, e \, f \, b \, L_f}{D^{4.9}} \quad \ldots\ldots\ldots\ldots (19)$$

Likewise, the annual cost of steel per foot of penstock is expressed by Equation (9). Let the length of penstock used for computing total weight be L_p, and the annual cost of the steel in the line will be:

$$E_p = E_{p_1} L_p = \frac{334 \, H \, D^2 \, a \, r \, L_p \, (1 + i)}{s_g \, e_j} \quad \ldots\ldots\ldots\ldots (20)$$

The total annual cost, E_t, of the entire penstock will be the sum of Equations (18), (19), and (20), or:

$$E_t = E_f + E_h + E_p \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

To determine the economic diameter equate the derivative of the total annual cost, E_t, with respect to D, to zero; thus:

$$\frac{dE_t}{dD} = -\frac{5.76392 \, K_s \, Q^{2.9} \, e \, f \, b \, L_f}{D^{5.9}} - \frac{74.82876 \, K_T \, Q^3 \, e \, f \, b}{D^5}$$

$$+ \frac{668 \, H \, D \, a \, r \, L_p \, (1 + i)}{s_g \, e_j} = 0 \quad \ldots\ldots\ldots\ldots (22)$$

In Equation (22), let,

$$G = 5.76392 \; K_s \; Q^{2.9} \; L_f \ldots\ldots\ldots\ldots\ldots\ldots (23a)$$

$$M = 74.82876 \; K_T \; Q^3 \ldots\ldots\ldots\ldots\ldots\ldots (23b)$$

$$J = e \; f \; b \ldots\ldots\ldots\ldots\ldots\ldots (23c)$$

and,

$$B = \frac{668 \, H \, a \, r \, L_p \, (1 + i)}{s_g \, e_j} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23d)$$

Then, substituting and solving for B, Equation (22) becomes of the form:

$$B = \frac{G \, J}{D^x} + \frac{M \, J}{D^y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

in which x and y are different exponents of D. Because of this difference, Equation (24) cannot be solved directly; but since the difference between them is only 13%, it is possible to assume that $x = y$, so that $B = \dfrac{J \, (G + M)}{D^x}$;

or, approximately:

$$D = \sqrt[x]{\frac{J\,(G + M)}{B}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Substituting $x = 6.9$, Equation (25) can be written as:

$$D = \sqrt[6.9]{\frac{J\,(G + M)}{B}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

approximately, or, in terms of all the fundamental factors involved:

$$D = \sqrt[6.9]{\frac{e\,f\,b\,(5.76392\,K_s\,Q^{2.9}\,L_f + 74.82876\,K_T\,Q^3)\,s_g\,e_j}{668\,H\,a\,r\,L_p\,(1 + i)}} \quad \ldots\ldots (27)$$

and, for greater accuracy, Equation (24) (with $x = 6.9$ and $y = 6.0$) can be solved for D by a trial-and-error method.

Considering Thickness of Shell.—In some instances, the thickness of the shell or of the plates of a penstock will be given instead of the head. As before (see Equation (9)) the annual cost of a 1-ft length of penstock is $E_{p1} = W_1\ a\ r$. Substituting the value of W_1 from Equation (7) (with $w = 490$), and simplifying:

$$E_{p1} = 128.282\ t\ D\ a\ r\ (1 + i) \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

The annual cost of a penstock of length, L_p, is:

$$E_p = E_{p1}\ L_p \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

Substituting Equation (28) in Equation (29) and finding the derivative of E_p with respect to D:

$$\frac{dE_p}{dD} = 128.282\ t\ a\ r\ L_p\ (1 + i) = B' \ldots\ldots\ldots\ldots\ldots (30)$$

in which B' is a substitution factor. In Equation (22), substitute Equation (30) for the term, $\dfrac{668\ H\ D\ a\ r\ L_p\,(1 + i)}{s_g\ e_j}$, so that B in Equation (24) becomes $\dfrac{B'}{D}$, and,

$$B' = \frac{G\,J}{D^{x-1}} + \frac{M\,J}{D^{y-1}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

If $x = y = 6.9$ as before, and if the fundamental factors for J, G, M, and B' are substituted logically, Equation (31) may be solved for D in a manner similar to Equation (26):

$$D = \sqrt[6.9]{\frac{J\,(G + M)}{B'}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

approximately, or, in terms of all the fundamental factors involved:

$$D = \sqrt[6.9]{\frac{e\,f\,b\,(5.76392\,K_s\,Q^{2.9}\,L_f + 74.82876\,K_T\,Q^3)}{128.282\,t\,a\,r\,L_p\,(1 + i)}} \quad \ldots\ldots\ldots (33)$$

In order to apply Equation (32) to a practical design, compute the constants, J, G, and M, and determine the economical diameter for different values of t in B' (see Equation (30)). With t and D known the permissible head may be computed from Equation (6) and this value determines the economic diameter at each station on the line where the head corresponds to the values of t and D. As in the case of Equation (24), Equation (31) (with $x = 6.9$ and $y = 6.0$) can be solved for D with greater accuracy by trial and error.

ACCURACY OF EQUATIONS (26) AND (32)

Computations show that the errors in the values of D computed from Equations (26) and (32), for $M = 0.5\ G$ and $M = G$, will not exceed -0.528% and -0.973%, respectively, compared to the accurate solution of those equations. For $M = 0$ corresponding to $K_T = 0$ and with $L = 1$ ft, the equations as given are accurate.

RELATIVE VALUES OF ECONOMIC DIAMETER

Table 1 illustrates the effect of varying the values of the expressions under the radical signs of Equations (11), (26), and (32). It shows that a considerable change in the individual values of the constants in the equations is necessary in order to affect the diameter appreciably. A change in the discharge is much more noticeable. Hence, extreme accuracy is not essential in any particular study, except that the discharge should be estimated as closely as possible.

COMPARISON OF RESULTS

In 1934, detailed studies were made of a large power development to determine the economic diameter of the penstocks. Subsequently, formulas were developed as outlined herein, using the same general principles as in the detailed studies. For convenience of comparison, the methods used in determining the economic diameter for this development are designated as A, B, and C. The same basic data were used in all three methods.

In Method A the annual cost of friction losses and of the penstock steel was considered. The annual cost of the entire length of penstock, and bend and entrance losses, in addition to the friction losses, was considered in

Method *B*; and, in Method *C*, a detailed study was made of the economic diameter of the penstock. Included in the latter were the annual costs of the penstock, friction, bend, and entrance losses as in Method *B* and, in addition, annual costs due to rack, valve, and cone losses. Water-hammer heads were computed separately for each assumed size of penstock. The economic size of the penstock, based on the minimum annual cost read from the Diameter-Total Annual Cost Curve, was 19.67 ft. The results of the computations by the three methods are summarized in Table 2.

TABLE 2.—COMPARISON OF METHODS TO DETERMINE ECONOMIC DIAMETER OF PENSTOCK

Method (1)	Equation used (2)	Diameter, D, in feet (3)	PERCENTAGE ERROR COMPARED WITH METHOD C: Diameter (4)	PERCENTAGE ERROR COMPARED WITH METHOD C: Total annual cost (5)
A	(11)	18.29	−7.02	+2.22
B	(26)	19.03	−3.25	+0.65
C	Detailed study	19.67	0	0

For this particular development, the bend losses formed a large proportion of the total losses. Hence, since bend losses are neglected entirely in Method *A*, it can be readily seen that the value of D, computed by Method *B*, should be larger than when computed by Method *A*. In the same way, Method *C* includes other losses in addition to those of Method *B*, and hence D, by Method *C*, is larger than by Method *B*. Another factor that must be considered is that Equation (26), for Method *B*, is approximate, and a more accurate solution would give a slightly higher value for D. Column (5), Table 2, shows the percentage errors in total annual cost of Methods *A* and *B* compared to Method *C*. The values of total annual cost, used to determine the percentage errors, were read from the Diameter-Total Annual Cost Curve for diameters corresponding to the three methods.

Table 2 shows that consideration of additional hydraulic losses and the resulting cost of lost power justifies additional capital expenditure for a larger penstock.

Use of Formulas.—The data for the illustrative example are, as follows: $Q = 400$ cu ft per sec; $e = 0.75$; $K_s = 0.401$; $K_e = 0.05$; $k_b = 0.25$; $\Delta = 25^\circ.9$; $K_T = K_e + K_b = 0.05 + 0.1342 = 0.1842$; $L_p = 100$ ft; $L_f = 130$ ft; $H = 130$ ft; $a = \$0.10$ per lb; $r = 0.17$; $s_g = 12\,000$ lb per sq in.; $e_j = 0.90$; $i = 0.20$; $f = 0.25$; and $b = \$0.007$ per kw-hr.

The entire length of the penstock, and the bend and entrance losses, in addition to the friction losses, will be considered in the example. Equation (26) is used to determine the economic diameter, D; but, first, it is necessary to solve for the several constants.

Substituting the foregoing values in Equations (23), and simplifying, $J = 13.14 \times 10^{-4}$; $G = 1\,058 \times 10^7$; $M = 88.3 \times 10^7$; and, $B = 16.4$. Then, from Equation (26), $D = 7.315$ ft; say, 7 ft 4 in.

Choice of Formula for Friction Loss

The Scobey formula (Equation (1)) was selected because it was the most authoritative and the newest available. Mr. Scobey deduced it after an extensive series of tests and a complete review and analysis of previous investigations. Among other factors, he allowed for the kinematic viscosity of water at 15° C (59° F), and for Reynolds' number. He also recommended proper coefficients for use in his formula, based on various classes of pipes and joints and ages of pipe, the coefficients being constant throughout the usual ranges of pipe diameters and water velocities.

Other Formulas for Economic Diameter of Steel Penstocks

Other formulas have been introduced by M. L. Enger[6], and H. K. Barrows[7], Members, Am. Soc. C. E., G. E. Lyon[8], Assoc. M. Am. Soc. C. E., and by Messrs. R. L. Daugherty[9], R. M. Peabody[9], B. F. Jakobsen[10], and W. F. Durand[11].

The Enger formula, as modified somewhat by W. P. Creager and J. D. Justin[12], Members, Am. Soc. C. E., is quite similar to Equation (33) except that they used the Chezy formula for friction loss. Professor Barrows gives a formula similar to Equation (11) except that he used the Weisbach formula for friction and assumed a value of efficiency, e, equal to 1.0. H. L. Doolittle, M. Am. Soc. C. E., outlines a method for the economic design of steel penstocks[13] and in their discussion[9] of that paper, Messrs. Daugherty and Peabody develop analytical solutions for the economic diameter.

Of the foregoing writers, none includes hydraulic losses other than those due to friction, and only Messrs. Creager and Justin attempt to give any specific data on the variation in yearly losses with the annual load factor.

Economic Velocity

Table 3 summarizes computations made to determine the most economic maximum velocity, V, for maximum penstock discharges, Q, of 400, 2 000 and 5 000 cu ft per sec, and heads for shell thickness, H, of 100 and 400 ft for an assumed set of conditions. The assumptions made for the computations are as follows: $K_s = 0.400$; $e = 0.85$; $f = 0.20$ corresponding approximately to a load factor, F, of about 50%; $b = \$0.003$ per kw-hr; $s_g = 15\,000$ lb per sq in.; $e_j = 0.80$; $a = \$0.10$ per lb; $r = 0.07$; $i = 0.10$; and $t =$ minimum shell thickness $= \frac{5}{16}$ in. A 1-ft length of penstock was assumed. Frictional losses only were considered. Except for Item No. 1, Table 3, required shell thicknesses as computed from Equation (6) were in excess of the $\frac{5}{16}$-in. minimum.

TABLE 3.—SUMMARY OF COMPUTATIONS FOR ECONOMIC VELOCITY

Item No. (1)	Maximum discharge, Q, in cubic feet per second (2)	Equation used to compute D (3)	Minimum shell thickness, t, in inches (4)	Economic diameter, D, in feet (5)	Economic velocity, V, in feet per second (6)	Item No. (1)	Maximum discharge, Q, in cubic feet per second (2)	Equation used to compute D (3)	Minimum shell thickness, t, in inches (4)	Economic diameter, D, in feet (5)	Economic velocity, V, in feet per second (6)
H = 100 FEET FOR SHELL THICKNESS						H = 400 FEET FOR SHELL THICKNESS					
1	400	(33)	$\frac{5}{16}$	7.40	9.31	4	400	(11)	Not required	6.03	14.03
2	2 000	(11)	Not required	14.49	12.13	5	2 000	(11)	Not required	11.85	18.13
3	5 000	(11)	Not required	21.30	14.04	6	5 000	(11)	Not required	17.42	20.98

Table 3 shows that V increases with Q and H. Inspection of the velocities in Column (6) indicate that they are fairly representative of existing practice. Economic velocities for conditions other than those assumed may be found in a similar manner, or proportioned from the results given in the table (see Equations (11) and (33)).

ANNUAL POWER LOSS, LOAD FACTOR, AND LOSS FACTOR

The average annual power loss is designated herein as P_a, and the maximum annual power loss for load factor, $F = 1.0$, is designated as P_m. Corresponding discharges are Q_a and $Q_m = Q$. Since discharge is assumed as proportional to power generated,

$$F = \frac{Q_a}{Q_m} = \frac{Q_a}{Q} \quad \dots\dots\dots\dots\dots\dots\dots\dots (34)$$

For a penstock of a given diameter, the head lost varies as $V^{1.9}$ and $Q^{1.9}$. The power lost varies as the product of head lost times discharge. Hence, the power lost varies as $Q^{2.9}$ for friction; and as Q^3 for bend, entrance, and other hydraulic losses where h_h varies as V^2 and Q^2. The equivalent annual discharge which will give a power loss, P_a, corresponding to the load factor, F, and average discharge, Q_a, is:

$$Q_e = \sqrt[2.9]{\frac{q^{2.9}{}_1 + q^{2.9}{}_2 + q^{2.9}{}_3 + \dots q^{2.9}{}_n}{N_1 + N_2 + N_3 + \dots N_n}} \quad \dots\dots\dots\dots\dots (35)$$

in which q_1, q_2, etc., are the discharges of the penstock, in cubic feet per second, for N_1, N_2, etc., hr, for the given period and load curve. For simplicity the exponent and root in Equations (35) and (36) may also be taken as 3 instead of 2.9 if desired. The relations between power losses, discharges, and loss factor is expressed by:

$$f = \frac{P_a}{P_m} = \frac{j\,Q^{2.9}{}_e}{j\,Q^{2.9}} \quad \dots\dots\dots\dots\dots\dots\dots\dots (36)$$

in which j is a constant. For a 1-ft length of penstock, a given diameter, D, and $f = 1.0$ for $F = 1.0$, the value of the constant, j, in Equation (36) is determined from Equation (4) to be:

$$j = 1.17631\ K_s\, e \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(37)$$

Messrs. Creager and Justin present data[14] and formulas which, reduced to the symbols of this paper, are as follows:

$$Q^3_a\, C_r = Q^3_e = Q^3_f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(38)$$

Their coefficient, C_r, varies with the load factor, F, and is given in their Fig. 43, which is used in their formula for the economic diameter of a steel penstock.[15] Assuming that $F = \frac{Q_a}{Q}$, a loss factor was computed and plotted as Curve D, in Fig. 1, from the relation:

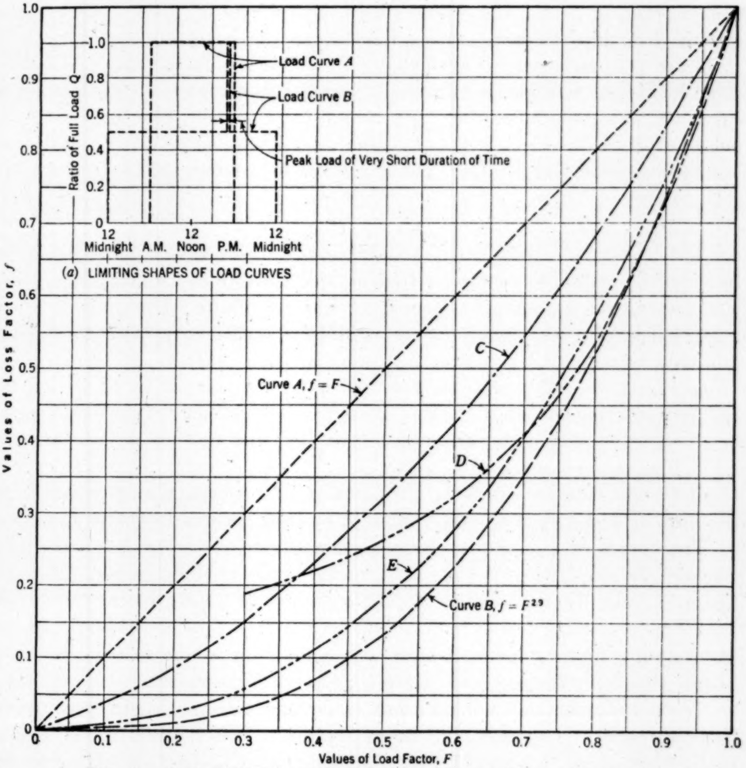

FIG. 1.—LOAD FACTOR-LOSS FACTOR CURVES FOR WATER CONDUITS

$$f = F^3\, C_r \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(39)$$

---

[14] Hydro-Electric Handbook, pp. 82 and 83, Equation 19, and Fig. 43.

[15] *Loc. cit.*, p. 414.

Loss Factor Data and Curves

Fig. 1 establishes the limiting loss factor curves, A and B, for steel penstocks corresponding to the given limiting shapes of Load Curves A and B in Fig. 1(a). Load Curve A is of rectangular shape and of constant peak load, whereas, Load Curve B is of rectangular shape with a peak load of uniform and very short duration, extending above the rectangular part. The equations of Curves A and B are, respectively, $f = F$ and $f = F^{2.9}$. Messrs F. H. Buller and C. A. Woodrow established similar limiting loss factor curves for transmission lines.[16] Curve C is taken from their average experience loss factor curve for transmission lines, the basic plotted points for which were computed from a series of actual and representative load curves of public utility plants serving diversified loads.

Curve D is an attempt to establish an average loss factor curve from data given by Messrs. Creager and Justin.[14] Curve E is a representative loss factor curve for water conduits, such as penstocks and tunnels, carrying water for public utility hydro-electric power plants serving typical diversified loads. It has been computed as follows: For any given load factor, F:

$$f_E = f^{1.5}{}_C \dots\dots\dots\dots\dots\dots\dots\dots (40)$$

in which f_C = the loss factor for transmission lines from Curve C for a given load factor, and f_E = the loss factor for water conduits. For cases in which a fairly accurate load curve can be established, the longer method of determining a value of Q_e should be used (see Equation (35)).

In Fig. 1, the value of Q for full-load water use is assumed to be that for full gate-opening, or for the rated horse-power of a turbine under its rated head. The friction head varies as $V^{1.9}$ or $Q^{1.9}$, and the power loss varies as $Q^{2.9}$. The power generated is assumed to be proportional to the water use. Until further data are available, the value of f for a typical load curve can be assumed to lie between Curves C and E, probably nearer to Curve E.

The curves of Fig. 1 may be used to estimate values of f for all water conduits in which the friction head varies approximately as V^2. The load factor, F, may be on a daily, weekly, monthly, or yearly basis. Mr. J. G. Tarboux uses a loss factor in formulas he develops for the economic size of transmission line conductors[17], in a manner similar to the method described in this paper, for the economic diameter of a steel penstock.

Table 4 summarizes computations made to check the accuracy of Equation (40) and of Curve E, Fig. 1, as applied to water conduits. A typical load curve[18] of the Alabama Power Company's system (mainly hydro-electric generation) was used as a basis. Its load factor was 0.795. Load curves for load factors of 0.321 and 0.550 were also drawn with shapes similar to that for a load factor of 0.795, except for the peak load. The loss factors for transmission lines in Column (3), Table 4, were computed on the assumption that the power loss varies as the square of the hourly ordinates (or load) of the load curve. The loss factors for water conduits in Column (5) were computed on the assumption that the power loss varies as the cube of the hourly ordinates (or load). Inspection of Table 4 shows that Equation (40) and Curve *E*, Fig. 1, are applicable in all ordinary cases.

ECONOMIC DIAMETER OF PENSTOCK FROM TOTAL ANNUAL COST CURVE

When it is desired to include costs other than those of, and in addition to, the frictional and hydraulic losses, and penstock steel, as given in the formulas heretofore developed, the procedure will be to assume several different penstock diameters and determine the annual cost for each diameter, including all the factors and elements of cost that vary with the diameter. These additional costs which are affected by the penstock diameter include: (*a*) Intake cost; (*b*) penstock valve costs; (*c*) annual saving in cost of concrete in the dam by using a larger penstock diameter; (*d*) cost of required generator flywheel effect for machine of desired rating, if more than that usually provided in a generator of normal design; (*e*) cost of surge tank, if any; (*f*) governor cost; and (*g*) cost of penstocks supports, etc. Referring to Item (*d*), the flywheel effect, is usually called $W R^2$, which equals the product of the rotating weight of generator rotor, in pounds, and the square of the radius of gyration, in feet.

The totals of the annual costs for all items for each assumed diameter are plotted as ordinates, with penstock diameters as abscissas. The minimum annual cost is found from the Diameter-Total Annual Cost Curve. For a study of this type, Equations (18), (19) and (20) will be found convenient to determine the annual costs of the frictional and hydraulic losses, and penstock steel, respectively.

ECONOMIC DIAMETER OF PENSTOCKS FOR PUMPING PLANTS

In general, the formulas developed in this paper for the economic diameter of steel penstocks for hydro-electric power plants apply to electrically operated pumping plants. In such a case, the annual cost of the power consumed in friction and other hydraulic losses, varies inversely as the over-all efficiency of the plant, *e*, since for a lower efficiency more power must be used to pump a given quantity of water against a given total head. On the other hand for a power plant, the annual cost of the power lost in friction and other hydraulic losses varies directly as the over-all efficiency, *e*, as shown by Equation (5). In Equation (11) for the economic diameter, *e* appears in the numerator of the expression under the radical sign, and in Equations (26) and (32), *e* as one factor in *J* appears in the numerator of the expression under the radical sign.

It follows, therefore, that in using the foregoing formulas to determine the economic diameter of penstock for a pumping plant, the efficiency, *e*, should be placed in the denominator of Equations (11), (26), and (32). In these formulas it is assumed that the head consumed in friction and other hydraulic losses forms only a small part of the static pumping head, and, therefore, that the size of the pumping motors and plant remains constant for a reasonable variation in the size of the penstock.

For a pumping plant with a very long penstock, and relatively low static head, it would be better to use the method outlined under the heading "Economic Diameter of Penstock from Total Annual Cost Curve", and include the annual cost of the pumping plant itself, and other variables, for each assumed diameter or plate thickness.

CONCLUSIONS

The formulas developed in this paper are general, but they are intended to apply particularly to the determination of the economic size of a penstock of uniform diameter for a hydro-electric power plant, particularly where the power-house is situated immediately down stream from the penstock intake section of the dam. Equation (11) or Equation (26) is to be used, depending on the accuracy desired, or the amount of data available.

For a long penstock, the diameter generally decreases toward the lower end, and the penstock is usually made in sections of uniform diameter and the same plate thickness, with transitions connecting the sections of different diameters. Equation (32) applies to this case.

ACKNOWLEDGMENTS

The subject of, and formulas developed in, this paper were suggested by studies made by the writers for a large power development. The senior writer, the late Mr. Charles Voetsch, passed away before he could review the paper entirely. The junior writer wishes to express herein his appreciation of the fine and unfailing spirit of co-operation and friendliness with which Mr. Voetsch drew on his wealth of experience and his valuable engineering library to assist or furnish data to all who desired aid in special problems. I. A. Winter, Assoc. M. Am. Soc. C. E., Senior Engineer, U. S. Bureau of Reclamation, made several valuable suggestions which have been incorporated in the paper. Power plant studies and designs of the U. S. Bureau of Reclamation, including those upon which this paper is based, are under the direction of L. N. McClellan, Chief Electrical Engineer. All studies and designs are under the general direction of J. L. Savage, M. Am.

Soc. C. E., Chief Designing Engineer; all engineering and construction work is under the direction of R. F. Walter, M. Am. Soc. C. E., Chief Engineer, with headquarters at Denver, Colo.; and all activities of the Bureau at the time this paper was prepared were under the general charge of the late Elwood Mead, M. Am. Soc. C. E., Commissioner of Reclamation. John C. Page, M. Am. Soc. C. E., Commissioner of Reclamation, with headquarters in Washington, D. C., is in general charge of Bureau activities.

APPENDIX

NOTATION

The symbols introduced in the paper are defined as follows:

a = the cost of steel in the penstock, in dollars per pound.

A = the cross-sectional area in a penstock, in square feet.

b = the value of power loss because of friction and other hydraulic factors, in dollars per kilowatt-hour.

B = a constant in Equation (26), defined by Equation (23d); B' = a constant in Equation (32), defined by Equation (30).

C_r = the coefficient used by Messrs. Creager and Justin, defined by Equation (38).

D = the economic inside diameter of a penstock, in feet.

e = the over-all efficiency of a plant to: (1) The point where power is sold, for a power plant; and (2) the point where power is purchased, for a pumping plant; e_j = the efficiency of the joints of a penstock, expressed as a decimal.

E = the annual cost (expense) of a penstock of length, L, in dollars; E_f = the annual cost of the power lost because of friction, in a penstock of length, L_f; E_{f_1} = the annual cost of the power lost because of friction in a penstock, 1 ft long; E_h = the annual cost of the power lost because of hydraulic factors other than friction (such as entrance losses, bend losses, etc.); E_p = the annual cost of the steel in a penstock of length, L_p; E_{p_1} = the annual cost of the steel in a penstock, 1 ft long; E_t = the total annual cost of a penstock of length, L; E_{t_1} = the total annual cost of a penstock, 1 ft long.

f = a loss factor, expressed as a decimal, corresponding to the load factor, F, and defined by Equations (36) and (38).

F = the load factor under which the plant operates (= average load ÷ maximum load); for a discharge proportional to the power generated, $F = Q_a \div Q$.

g = the acceleration due to gravity (= 32.16).

G = an algebraic substitution factor in Equations (26) and (32), as defined by Equation (23a).

h = loss of head, in feet; h_f = the head lost in friction, in a penstock of length, L_f; h_{f_1} = the head lost in friction, in a penstock 1 ft long; h_h = the head lost because of hydraulic factors other than friction; h_t = the total head lost because of friction and hydraulic factors; h_b = the additional head lost, due to the introduction of a bend in an otherwise straight penstock; h_e = the head lost at the entrance to a penstock or intake.

H = the average head, on the penstock, including water-hammer effect, in feet (weighted average to be used if necessary).

i = percentage of overweight of steel in a penstock, due to laps, cover-plates, rivets, welds, etc., expressed as a decimal.

j = a constant in Equation (36) defined by Equation (37).

J = an algebraic substitution factor in Equations (26) and (32), as defined by Equation (23c).

k_b = a constant in Equation (14) defined by $k_b = K_b \div \sqrt{\frac{\Delta}{90}}$; usual approximate value = 0.25.

K = a coefficient; K_b = a constant that modifies the expression for head loss when bends are introduced in an otherwise straight pipe (see Equation (14)); K_e = a constant that modifies the expression for head loss at the entrance to a penstock (see Equation (15)); K_s = a general coefficient in the Scobey formula (Equation (1)) which determines the head lost in friction; K_t = a constant in Equation (13) to account for hydraulic effects other than bend losses and entrance losses; K_T = the sum of all constants for hydraulic losses, as defined by Equation (13).

L = length, in feet: L_f = length of penstock used to compute friction loss when it differs from L_p; L_p = length of penstock used to compute the weight of steel when it differs from L_f;

M = an algebraic substitution factor in Equations (26) and (32), as defined by Equation (23b).

N = time, in hours, for a given period and load curve, during which the penstock discharge is q (q_1, q_2, etc., correspond with N_1, N_2, etc.).

P = annual power lost, in kilowatt-hours: P_a = average loss due to friction and hydraulic factors, at the load factor, F; P_f = loss due to friction in a penstock of length, L_f; P_{f_1} = loss due to friction in a penstock 1 ft long; P_h = loss due to hydraulic factors other than friction; P_m = loss due to friction and other hydraulic factors, at full or maximum load, corresponding to the discharge, Q, and the load factor, $F = 1.0$.

q = discharge of a penstock, in cubic feet per second, during a stated time, N, and for a given period and load curve; q_1, q_2, etc., correspond to N_1, N_2, etc.

Q = the rated discharge of a penstock, in cubic feet per second, corresponding to full gate-opening, or the rated horse-power of the connected turbine or turbines (or as limited by the generator capacity), when operating under rated or normal head (in this paper, penstock discharge is assumed to be proportional to the power generated, and Q is assumed equal to Q_m); Q_a = average discharge corresponding to the average power generated during the period and for the load curve considered; Q_e = the equivalent discharge, for the period and load curve considered, to give a power loss for the period equivalent to the actual power loss for the period and the load curve considered (see Equation (35)); Q_m = the maximum discharge for the load factor, $F = 1.0$ (Q_m is assumed equal to Q).

r = the ratio of the annual fixed, operating, and maintenance charges to the construction cost of the penstock.

s = unit stress, in pounds per square inch; s_g = the gross allowable tension in the penstock steel.
t = the thickness of the steel in the penstock, in inches.
V = the velocity of the water in the penstock, in feet per second, corresponding to the discharge, Q.
w = weight of steel, in pounds per cubic foot (= 490).
W = weight of steel, in pounds, in a section of a penstock of length, L; W_1 = weight of steel in a 1-ft section of a penstock.
x = a variable exponent of diameter, D (see Equations (24), (25), and (31)).
y = a variable exponent of diameter, D (see Equations (24) and (31)).
Δ = the angle of bend in a penstock, in degrees.

DISCUSSION

R. A. MONROE,[19] M. AM. SOC. C. E. (by letter).—As noted by the authors, several formulas for computing the economic diameter of steel penstocks have previously been presented. All these formulas are based on the same fundamental principle, namely, that the most economic size of penstock is that for which its annual cost, plus the value of the power lost in friction, is a minimum. For any given set of conditions all will give practically identical results.

The authors have used the Scobey formula for flow in steel pipe lines for the stated reason that: "It is the most authoritative and the newest available." However, the use of the Weisbach formula,

$$Q = \frac{f\,L\,V^2}{2\,g\,D} \quad \text{.......................} \quad (41)$$

(in which f is a friction factor) leads to a considerably simpler mathematical expression for the economic diameter with no appreciable sacrifice in accuracy, providing the factor, f, is properly chosen for the range of penstock diameters being considered. This simplification is particularly desirable when attempting to develop an expression which will include the hydraulic losses, h_h, other than those of friction, all of which are assumed to vary as the square of the velocity head.

The introduction of the load-factor loss curves to enable a quick approximation of the flow for which the economic diameter should be determined is a novel idea. It should be noted, however, that a hydro-electric plant which is tied into a large interconnecting system is seldom operated to produce an output that is proportional to the system load. When ample water is available the hydro-electric plant is usually operated at a high load factor at or near its point of best efficiency for most of the day, dropping off for only a short period when the system load is at a minimum; the peak load of the system is carried by steam plants operating on a very low load factor. During low-flow periods, this method of operation is reversed, particularly where facilities exist for forebay pondage, the hydro-electric plants being operated on the system peak whereas the base load is carried by steam.

In a hydro-electric plant having several units a reduction in output is usually effected by shutting down some of the units and continuing operation of the units remaining in service at the point of best efficiency. In this case the penstock loss is not substantially reduced providing the units are served by separate penstocks. A further point to consider is that peak power is always worth considerably more per kilowatt-hour than the average output of the system, as is indicated by the demand charge which is usually embodied in electric-rate schedules. Consideration of these facts will lead to the selection of a somewhat larger flow on which to base an economic design than would be chosen if the criterion selected was that flow for which the total friction loss is equal to the friction of the actual variable flow. The engineer can usually determine the proper basis of design for any particular case, but as a general proposition it appears that the economic design of a penstock should be based on a flow approaching that which will be utilized by the turbines at the point of best efficiency.

---

[19] Head Water Control Engr., TVA, Knoxville, Tenn.

The value of power which should be used in the formula for economic penstock design cannot be determined readily but its exact value is not important since results are affected only in proportion to the seventh root of this factor. The same consideration applies to the ratio of fixed charges to total cost.

An easily applied formula for determining the economic diameter of a steel penstock is very desirable and convenient, particularly for preliminary studies. For the final design of a pipe line in which the various factors become definitely established, it seems quite desirable to make a detailed calculation of the cost and of the hydraulic losses for at least three sizes of penstock. Such a computation will permit a curve to be drawn showing the variation in cost of output in terms of diameter of penstock, which will afford a definite basis for the selection of the proper size. It also makes it possible to take into account many factors which do not lend themselves to formalization. It may perhaps be noted that since the cost curve for varying diameters is usually comparatively flat, the very real advantage of keeping initial costs to a minimum will often cause the selection of a pipe diameter considerably smaller than that shown theoretically as the most economical on the basis of estimates of the future value of power.

WILLIAM E. RUDOLPH,[20] M. AM. SOC. C. E. (by letter).—The application of one of the equations in this paper can be demonstrated with reference to a problem that often arises in penstock design—that of the single pipe line as compared to multiple pipe lines. Especially is this important in hydro-electric development in South America, where it is quite common, first, to install machines for utilizing only a portion of the potential power at a site, and, later, to install other machines to reach the full capacity of the normal water flow. Where there is to be a considerable lapse of years between the first and the later construction stages of a hydro-electric project, the penstock is built of sufficient capacity for the initially installed units only. However, there are instances in which the second stage of development follows within a few years of the first, as, for example, in the development of a mine where the tonnage of ore to be treated increases rapidly. In such cases it is sometimes advantageous to build the penstock for the final project during the first stage of the development, because of the saving in cost of a single pipe line as compared to that of multiple pipe lines.

The writer has been trying to apply the formulas of this paper to a particular problem under consideration. He began by determining the economic diameter of penstock for the amount of power to be installed at once, and then for a single pipe line for the ultimate capacity (which in this case was exactly double the initial installation). The difference in ultimate capital investment between a single large pipe line and (in this case) two smaller pipe lines, was thus estimated. Such definite saving *n* yr hence, was converted back to its present value, ϕ, using the rate of interest applicable. Then, for the pipe line of the capacity of the present installation only, the annual cost of the penstock is defined by Equation (21). For the pipe line of a capacity of present, plus future, installation, the annual cost of the penstock (accurately enough for practical purposes), is:

---

[20] Shoreham, N. Y.

$$E_t = E_f + E_h + E_p - \frac{\phi}{n} \quad\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

The smaller annual cost determines the more advantageous installation. In the case under consideration, n being only 2.5 yr, the greater capital expenditure for the full-sized penstock, with the initial installation, appeared to be justified.

PETER BIER,[21] ESQ. (by letter).—Within certain limitations, the economic diameter of steel penstocks and pump discharge lines can be determined rationally by means of this interesting paper. Equation (11) has been derived by using Equation (6) for the calculation of the plate thickness corresponding to a given head. For low-head developments where the plate thickness is not a function of the head, but an arbitrary minimum established to satisfy the requirements of rigidity, fabrication standards, or long life, Equation (11) will not give the proper answer.

An example of a welded-steel discharge pipe for a pumping plant will illustrate this point. Let $Q = 150$; $K_s = 0.36$; $e = 0.71$; $F = 0.425$; $f = 0.42$; $b = \$0.0026$; $s_g = 13\,500$ lb per sq in.; $e_j = 0.90$; $a = \$0.09$; $H = 150$ ft; $r = 0.07$; $i = 0.05$; $L = 1\,920$ ft; and, $t = 0.25$ in. (minimum).

From Equation (11) modified for pump lines:

$$D = 0.50218 \sqrt[6.9]{\frac{0.36 \times 2\,044\,800 \times 0.42 \times 0.0026 \times 13\,500 \times 0.9}{0.09 \times 150 \times 0.07 \times 1.05 \times 0.71}} = 5.44 \text{ ft}$$

With the same data a detailed analysis, based on the total annual cost per foot of pipe, including annual fixed, operating, and maintenance charges, gives the following values, for the various diameters considered:

Diameter of pipe, in feet	Total annual cost, in dollars per foot of pipe
4.75	1.65
5.25	1.50
5.75	1.47
6.25	1.49
6.75	1.56

According to the foregoing data, the economic diameter would be 5.75 ft as compared to 5.44 ft obtained from Equation (11). The discrepancy is due to the fact that in the detailed analysis the diameter derived was not a function of the head and the allowable unit stress as in Equation (11), but resulted from using a minimum plate thickness of 0.25 in. for practical reasons.

In the foregoing example, Equation (6) would yield different plate thicknesses for the varying heads along the profile of the pipe line, with a maximum value of $\frac{3}{16}$ in., which, however, falls short of the practical requirements. Since the values included in Equation (6) enter into Equation (11), this cannot be used for pipes under low heads, where values of t will fall below the minimum plate thicknesses established for reasons other than the requirements of head or the allowable tension in the plate.

---

[21] Engr., U. S. Bureau of Reclamation, Denver, Colo. Approved for publication by the U. S. Bureau of Reclamation.

For low-head plants the economic diameter should be determined from Equation (33) by substituting the desired plate thickness into the equation. For the pumping line used in the foregoing example where only pipe friction losses are considered, Equation (33) may be written as follows:

$$D = \sqrt[5.9]{\frac{0.42 \times 0.0026 \times 5.76392 \times 0.36 \times 150^{2.9}}{0.71 \times 128.282 \times 0.25 \times 0.09 \times 0.07 \times 1.05}} = 5.76 \text{ ft}$$

This closely checks the 5.75-ft diameter obtained from the detailed analysis.

Theoretically, the 0.25-in. plate thickness substituted in Equation (6) would give, for $D = 5.75$ ft and $s_g = 13\,500$:

$$H = \frac{0.25 \times 2 \times 13\,500 \times 0.9}{0.4335 \times 5.75 \times 12} = 203.4 \text{ ft}$$

which is the head to which the 0.25-in. shell may ordinarily be subjected if no other considerations enter into the problem.

For pipe lines supported on piers or columns with long spans, a considerable error may be introduced in these equations by using the value, i, which consists of additions to the weight of pipe due to laps, butt straps, stiffener rings, etc. Values of i may vary from 0.05 to 0.25, depending on the span or type of support used. The trend in modern steel-pipe design is to use long spans between supports. This necessitates not only heavy stiffener rings and supports, but also a pipe shell of increasing thickness toward the point of support to reduce the stresses in the shell adjacent to the supporting rings. In such cases it is difficult to formulate the plate thickness or unit cost of the pipe for introduction into the equations unless some preliminary computations or designs are first made for a typical span, and the average plate thickness or cost determined therefrom.

The method presented by the authors should be more economical to use than the detailed analysis after one becomes familiar with its application. The lengthy equations, however, will greatly increase the chance of error. On important and costly installations which justify a more extended analysis it may be advisable to determine the economic diameter first with the authors' method and then check the result with a detailed analysis. By thus limiting the necessary computations to a smaller number of diameters in the detailed analysis, some economy in time may be effected and the result would be more reliable.

Great accuracy on the other hand is not important since certain factors greatly influencing the determination of the economic diameter, such as the numerical relation between the value of power lost in friction and the cost of the pipe line, are necessarily based on more or less accurate estimates, which are subject to change.

Adolpho Santos, Jr.,[22] **Assoc. M. Am. Soc. C. E.** (by letter).—The subject of this paper belongs to that class of engineering problems which, for their proper solution, require the exercise of judgment. Affected as they are by matters of opinion and by a multiplicity of varying, complex, and, sometimes, conflicting factors, such problems cannot be solved with any high degree of precision no matter how dexterous one may be in the use of mathematical tools. Attempts to increase the precision beyond the limits imposed by the nature of the problem are illusory and only add to the complexity. The principal merit of mathematical analyses of such problems is as an aid in understanding them and in reaching sound judgment.

The authors state that, as computed by their formulas, the economic diameter of a penstock for a certain development shows a difference of only 3.25%, as compared to the diameter determined from detailed studies. To the writer this only proves that, starting from identical, basic, and assumed data, the formulas give results which agree with those obtained from detailed studies. It does not prove that the assumptions were correct. Certain of these assumptions, and the haze of uncertainty surrounding them, will be discussed briefly.

The selection of Scobey's formula for estimating the penstock friction loss is justified. It is indeed authoritative, but any estimate of friction-head loss based on it, intended to serve as the basis of economic studies, is nothing more than a forecast of future conditions and, as such, it is not necessarily accurate. The coefficient, K_s, depends on the class of pipes and joints but varies considerably for different penstocks of the same class, and, in many cases, the class itself is only definitely known after the final award of the contract, as joints and other details differ between different manufacturers. It is also known that K_s increases with the age of the penstock, the rate of increase depending on the size of the penstock, the type of protective cover of the internal surface, the quality of the water, climate, etc. The writer knows of cases in which the rate of increase of K_s is 10% each year, and of an extreme case in which it is more than 20% per year. The question arises, therefore, as to what rate of increase and what age of the penstock should be assumed for purposes of economic studies.

The assumption that the friction loss in the penstock varies as the 1.9 power while the other hydraulic losses vary as the square of the velocity seems to be an unwarranted refinement in economic studies because: (*a*) K_s cannot be predicted accurately; (*b*) "* * * it must not be overlooked that the individual values of z vary all the way from 1.73 to 2.14", as Scobey has stated;[23] (*c*) the refinement adds greatly to the complexity of the problem, as will be seen by comparing Equation (11) with Equations (24) to (27); and (*d*), the gain in precision, if any, is negligible.

It would be preferable to select a value of K_s high enough to cover the total losses, particularly in the more common developments where the bend losses are only a small proportion of the total. In the relatively few cases where the bend losses form a great proportion of the total it might be better, in order to avoid unnecessary complexity, to adopt some formula other than that of Scobey in which the friction loss is made to vary as the square of the velocity.

[23] "The Flow of Water in Riveted Steel and Analogous Pipes", by Fred C. Scobey, M. Am. Soc. C. E., *Technical Bulletin No. 150*, U. S. Dept. of Agriculture, January, 1930, p. 81.

There is also the question of the discharge which, as the authors state, "should be estimated as closely as possible". For the purpose of economic studies, should the maximum overload, the rated, the most frequent, or some other value of discharge, be assumed? This question is answered partly by the introduction of a factor to take care of the effect of the load factor. The question is not precisely answered, however, because to apply this factor it is necessary to make assumptions regarding the future loading of the unit, and this, again, requires the introduction of the element of judgment. In any case, no matter what value of discharge is selected, the fact remains that the horse-power and efficiency guaranties given by the turbine manufacturers are subject to a certain tolerance, so that at the time of making the economic studies the discharge is not known with a precision greater than 1 to 2 per cent.

In order to determine the thickness of the steel pipes it is necessary to assume a value for the head. This is not quite as simple as it appears. For reasons given elsewhere[24] it is considered that high-head penstocks, at least, should be designed to resist, without appreciable deformation, the stresses caused by the extreme pressures resulting from accidental conditions. These extreme pressures may arise from a variety of causes, some of which depend on the maximum discharge whereas some do not. The probability of any one assumed accidental condition arising during the life of the penstock is a matter for speculation so that weighting is difficult. Then there are the questions of maximum allowable stress intensity under static pressure in the lower part of the penstock, and of minimum thickness to prevent collapse due to vacuum, and as protection against corrosion, in the upper part. As a result of these and other factors it is a nice problem for the judgment and experience of the engineer to determine just which head to use.

All other factors entering into the problem, such as, over-all efficiency of the plant; loss factor corresponding to the load factor under which a plant operates (what should one assume as the period of the average load and as the interval of the maximum load?); value of power lost; unit cost of steel (which varies with the diameter of the penstock not only in purchase price, but also as affected by erection costs); percentage of over-weight; etc., are, each and all, subject to varying degrees of uncertainty. This being the case it follows that the calculated economic diameter is also uncertain and can serve only as a guide to judgment. The probable error or degree of uncertainty of the computed value can be estimated by the well known law of the propagation of errors.

---

[24] "High-Head Penstock Design", by Messrs. Billings, Dodkin, Knapp, and Santos; Symposium on Water-Hammer, A. S. M. E., Hydraulic Div., and Am. Soc. C. E., Power Div., p. 29 *et seq.*

For purposes of illustration the writer considers the data given by the authors and assumes certain values for the probable errors of some of the factors: $Q = 400 \pm 4$ cu ft per sec; $e = 0.75 \pm 0.015$; $K_s = 0.401 \pm 0.020$; $K_e = 0.05 \pm 0.005$; $k_b = 0.25 \pm 0.025$; $H = 130 \pm 10$ ft; $i = 0.20 \pm 0.05$; and, $f = 0.25 \pm 0.025$. It will be assumed that the remaining factors: Δ, L_p, L_f, a, r, s_g, e_j, and b are known precisely (which is not the case), and are as given by the authors.

Applying to these data, the law of the propagation of errors, the writer finds from Equation (2) that the head lost due to friction is 0.421 ± 0.022 ft. Similarly, from Equations (2) and (16), it is found that the total head loss is 0.680 ± 0.030 ft. In other words, the probable error of the friction loss is about ± 5.2% and that of the total loss, ± 4.4%, thus indicating that the two methods of arriving at the head loss are of about the same degree of precision. The reason for the large difference in the actual loss as computed by the two methods lies in the fact that the bend losses form a high proportion of the total. This difference could have been made to disappear by increasing K_s proportionately.

Keeping the same number of significant places as the authors, it is found, on the basis of Equations (23) and (26), that $G = 1\,058 \times 10^7 \pm 61 \times 10^7$; $M = 88.3 \times 10^7 \pm 7.3 \times 10^7$; $J = 13.14 \times 10^{-4} \pm 1.34 \times 10^{-4}$; $B = 16.4 \pm 1.4$; and $D = 7.315 \pm 0.154$ ft. This shows that the probable error of the computed value of the economic diameter is about ± 2 in., even when it is optimistically assumed that one-half the factors affecting the result are known exactly. If the retardation coefficient is increased by 15% (and there is reason for doing this when the bend losses are known to be high), thus making $K_s = 0.461$, the diameter computed by the simpler Equation (11) is 7.10 ft, with about the same probable error as the value previously determined.

While on the subject of precision of computations the writer would remark that in deducing Equation (4) from Equation (3), there is no justification for increasing the number of significant places in the constants from three (62.5 and 0.746) to six (1.17631). Similarly, in going from Equation (16) to Equation (17) the increase in the number of significant figures from four to seven is not justified. It is an old rule that "one can never acquire in the product more accurate places than there are in the poorer of the two factors". Division comes under the same rule.

The writer has tried to emphasize the limitations of all formulas purporting to give, directly, the economic diameter of steel penstocks. A further limitation of any such formulas results from the fact that they give one, and only one, value for the diameter, whereas, at least in the case of high-head penstocks, it will be found more economical to vary the diameter with the head. In such cases, it will also be found expedient to proportion the diameters and the length of each reach of different diameter, aside from economical considerations, in such a manner as to reduce to a minimum the pressures resulting from the water-hammers produced during accidents.

JOSEPH D. LEWIN,[25] JUN. AM. SOC. C. E. (by letter).—In that it permits taking into consideration such new factors as bend losses, entrance losses, etc., the development of penstock analysis in this paper is a very interesting one. In the form in which the authors have presented their analysis its application is limited to uniform (that is, horizontal) penstocks. A few changes in the interpretation of the present analysis are sufficient to extend its application to all horizontal and inclined penstocks.

Friction Loss and Annual Cost of Penstock.—In 1914, Professor A. Ludin published his formula[26] which, in the notation of the paper, may be written:

$$D = \frac{\sqrt[7]{101.3\, e_T\, e_G\, e_j\, s_z\, b_w\, T}\ \sqrt[7]{\dfrac{(Q')^3}{H}}}{(1+i)\ \gamma\ C^2_z\ a_s} \ldots\ldots\ldots\ldots\ldots (43)$$

in which e_T = the efficiency of the turbines, in decimals; e_G = the efficiency of the generators, in decimals; e_j = the efficiency of the joints, rivets, etc., in decimals; s_z = allowable stress, in kilograms per square centimeter; b_w = the value of the power at the generators, in marks per kilowatt-hour; T = hours of use; γ = the specific weight of steel (= 7.9); C_z = the friction coefficient in the Chezy formula; a_s = the annual cost of a ton of steel, in marks per ton; and Q' = equivalent discharge, in cubic meters per second. Converted into the units of this paper, Equation (43) becomes:

$$D = 0.56682\ \sqrt[7]{\frac{e\, b\, s_g\, e_j\, T}{a\, r\, C^2_z\, (1+i)}}\ \sqrt[7]{\frac{(Q')^3}{H}} \ldots\ldots\ldots\ldots (44)$$

The differences in the root, in the constant, and in the friction coefficient are due to the use of different equations for determining the friction losses.

The authors used the Scobey formula, Equation (1), and Professor Ludin, the Chezy formula,

$$h_f = \frac{4\ V^2}{C^2_z\ D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

For turbulent flow with rough walls, the exponent, 2, for the velocity seems preferable.

For the penstock under consideration the economic conditions of location, elevation, transportation, etc., determine the first radical in Equation (44) and the corresponding quantity in Equation (11), so that they become constant, which may be expressed, respectively, by the symbols, K'_r and K_r. The economic diameter can be expressed as:

$$D = K_r \sqrt[6.9]{\frac{Q^{2.9}}{H}} = K'_r \sqrt[7]{\frac{Q^3}{H}} \ldots\ldots\ldots\ldots\ldots (46)$$

---

[25] Hydr. Designer, Phœnix Eng. Corp., New York, N. Y.

[26] "Die Wirtschaftliche Bemessung von Triebwasserleitungen" von A. Ludin, *Zeitschrift für das gesammte Turbinenwesen*, 1914, No. 13; also, "Wasserkraftanlagen", von A. Ludin, Berlin, 1934, pp. 194–197.

For pressures greater than 300 ft, and for the economic conditions prevailing in Central Europe, Professor Ludin[26] developed the formula:

$$D_m = \sqrt[7]{\frac{5.2\,Q^3}{H}} = 1.26557\ \sqrt[7]{\frac{Q^3}{H}} \quad \text{.................} (47)$$

in which D_m = the economic inside diameter, in meters. The solution of Equation (47) is greatly facilitated by the preparation of a nomogram such as Fig. 2. Equation (11) may seem very complicated, and it will be quite difficult to obtain correct data for the value of the power and costs of the penstock. The value of K_r or K'_r, however, remains nearly unchanged. If the steel costs, a, are greater, the price of power will increase accordingly; or, if the load factor, F, is small (peak power plant), the price of the peak energy, b, will be high too.

This is the reason why Equation (47) is correct for most European penstocks. For all cases with pressures less than 300 ft (100 m) Dr. Bundschu[27] advises heads of 300 ft. Using the values given in the paper under the heading, "Use of Formulas," as prevailing in the United States, Equation (11) becomes:

$$D = 1.33822639\ \sqrt[6.9]{\frac{f\,Q^{2.9}}{H}} \quad \text{.....................} (48)$$

The corresponding diameters can be obtained from Fig. 2 which must be changed accordingly. In Fig. 2, there are two scales for diameters, the left for the European conditions (Equation (47)), and the right for the American conditions (Equation (48)). In the computation the writer prefers to use "the equivalent discharge," Q'_e (discussed subsequently), instead of the authors' quantity, $f\,Q^{2.9}$; but for the purpose of checking the values given in Table 3, with $f = 0.25$, a scale corresponding to,

$$D = 1.38823\ \sqrt[6.9]{\frac{0.25\,Q^{2.9}}{H}} = 1.13555\ \sqrt[6.9]{\frac{Q^{2.9}}{H}} \quad \text{...........} (49)$$

is drawn on the right in Fig. 2. The scales for Equations (48) and (49) differ only by the difference in the constant. Table 5 demonstrates how very closely the computed values coincide with those found nomographically.

FIG. 2

Fig. 2 will be the correct dimensions of a penstock under normal economical conditions in Europe, or in the United States, respectively. Should the location of the penstock under consideration cause changes in Equations (47) or (48) a new scale of diameter can be found very easily, in 25 to 30 min, as follows: Substitute the new data in Equation (11) or in Equation (44), depending on whether the Scobey or the Manning formula is preferred. The solution will have the form of Equation (46). The discharge, Q, will be:

$$Q = \sqrt[2.9]{H \left(\frac{D}{K_r}\right)^{6.9}} = \sqrt[3]{H \left(\frac{D}{K'_r}\right)^{7}} \quad \ldots\ldots\ldots\ldots\ldots (50)$$

Next, applying Equation (50), find the discharges for values of $D = 0.1$, 1.0, and 10.0; and $H = 100$, 1 000, and 10 000. The lines connecting the corresponding points, H and Q, in the nomogram will intersect in $D = 0.1$, 1.0, and 10.0. This gives the place of the new D-scales and the size of the unit. The method thus described has the advantage that every D-point is found by intersecting three lines, and thus a double check is possible.

Losses Other Than Those Due to Friction.—The authors limit their analysis to penstocks of uniform diameter, or to a horizontal penstock only. Considering Equation (46) for a constant discharge, Q, the diameters at any elevation, u or v, may be determined by the formulas:

$$D_u = K_r \sqrt[6.9]{\frac{Q^{2.9}}{H_u}} = K \sqrt[6.9]{\frac{1}{H_u}} \quad \ldots\ldots\ldots\ldots\ldots (51a)$$

$\left(\text{or } K'_r \sqrt[7]{\frac{Q^3}{H_u}} = K \sqrt{\frac{1}{H_u}}\right)$; and, similarly,

$$D_v = K \sqrt[6.9]{\frac{1}{H_v}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (51b)$$

$\left(\text{or } K \sqrt[7]{\frac{1}{H_v}}\right)$ in which $K = K_r \sqrt[6.9]{Q^{2.9}}$ (or $K'_r \sqrt[7]{Q^3}$). The relation between two diameters at the different elevations may be expressed as:

$$D_v = D_u \sqrt[6.9]{\frac{H_u}{H_v}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

$\left(\text{or } D_v \sqrt[7.0]{\frac{H_u}{H_v}}\right)$.

In an inclined penstock, therefore, the different diameters, D_v, are determined by Equation (52) after one diameter, D_u, has been computed. Consequently, Equations (27) and (33) of the paper can be used without applying the limitations fixed by the authors. This general application of bend-loss formulas is the new idea introduced by the authors in the analysis of penstocks.

Example.—It is intended to design a penstock, a part of which is horizontal and a part inclined. The angles of bends, and their elevations, are known. Applying Equation (52), reduce the different diameters to a single diameter, D_u, at a basic plane of reference, Elevation u, the result is a series of formulas for annual friction loss, as follows (see Equation (19)):

$$E_{f1} = \frac{1.17631\ K_s Q^{2.9} e f b L_1}{\left(D_u \sqrt[6.9]{\frac{H_u}{H_1}}\right)^{4.9}} = \frac{1.17631\ K_s\ Q^{2.9}\ e f b}{\sqrt[6.9]{H^{4.9}{}_u}}\ \frac{L_1 \sqrt[6.9]{H^{4.9}{}_1}}{D^{4.9}{}_u} \quad \ldots (53)$$

or, substituting $\kappa_f = \dfrac{1.17631\ K_s\ Q^{2.9}\ e f b}{\sqrt[1.41]{H_u}}$:

$$E_{f1} = \kappa_f\ L_1 \frac{\sqrt[1.41]{H_1}}{D^{4.9}{}_u} \quad \ldots\ldots (54)$$

For any inclined part of the penstock the annual cost of friction loss will be:

$$E_{fn} = \frac{\kappa_f\ L_n \sqrt[1.41]{H_n}}{D^{4.9}{}_u} \quad \ldots\ldots (55)$$

for any bend loss, at any elevation:

$$E_{b1} = \frac{18.70719\ Q^3\ e f b}{\left(\sqrt[6.9]{\frac{H_u}{H_1}}\ D_u\right)^4}\ K_{b1}$$

or substituting $\kappa_b = \dfrac{18.70719\ Q^3\ e f b}{\sqrt[1.72]{H_u}}$:

$$E_{b1} = \frac{\kappa_b\ K_{b1} \sqrt[1.72]{H_1}}{D^4{}_u} \quad \ldots\ldots (56)$$

In a penstock consisting of the three sections shown in Fig. 3, the total annual cost of the entire penstock will be the sum of a series of formulas similar to Equations (55) and (56), thus:

$$E_{\text{Total}} = E_{f1} + E_{f2} + E_{f3} + E_{b1} + E_{b2} + E_p + E_e \quad \ldots\ldots (57)$$

The economic diameter is determined by the first differentiation of Equation (57); thus:

$$\frac{dE_t}{dD_u} = -\frac{\kappa_f\, 4.9}{D^{5.9}{}_u}\left[\sqrt[1.41]{H_1}\, L_1 + \sqrt[1.41]{H_2}\, L_2 + \sqrt[1.41]{H_3}\, L_3\right] - \frac{\kappa_b\, 4}{D^5{}_u}\left[\sqrt[1.72]{H_1}\ K_{b1} + \sqrt[1.72]{H_2}\ K_{b2}\right] + B = 0 \quad \ldots\ldots (58)$$

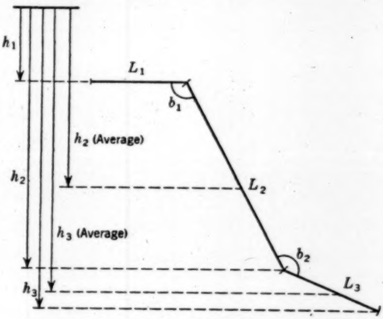

FIG. 3.—SCHEMATIC LAYOUT OF THE PENSTOCK

in which B is defined by Equation (23d). Substituting,

$$U = \frac{4.9\,\kappa_f}{D^{5.9}_u}\left[\sqrt[1.41]{H_1}\,L_1 + \sqrt[1.41]{H_2}\,L_2 + \sqrt[1.41]{H_3}\,L_3\right] \quad \ldots\ldots\ldots (59a)$$

and,

$$V = \frac{4\,\kappa_b}{D_u^5}\left[\sqrt[1.72]{H_1}\,K_{b1} + \sqrt[1.72]{H_2}\,K_{b2}\right] \quad \ldots\ldots\ldots\ldots (59b)$$

in Equation (58) and solving for B,

$$B = \frac{U}{D^x} + \frac{V}{D^y} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (60)$$

which corresponds to Equation (24) and can be solved in a similar manner to yield:

$$D_u = \sqrt[6.9]{\frac{U + V}{B}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (61)$$

Since κ_f, H, L, K_s, and K_b, corresponding to Equation (27), are definite constant values, Equation (61) can be solved. It is also advisable for comparison to compute Equation (61) changing the root from 6.9 to 6.0. so that the limits of the error may be judged.

The foregoing development of the basic formula, Equation (27), extends its application to all penstocks in which H is greater than 300 ft.

Discussion of Fig. 1.—In regard to the Q-value to be used in Equation (43) Professor Ludin prescribes the determination of the equivalent discharge:

$$Q' = Q_{\text{Equivalent}} = \sqrt[3]{\frac{\Sigma\, q^3}{\Sigma\, t}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (62)$$

in which q = partial discharge, in cubic feet per second, during a time interval,[28] t, for every different case.

The authors' computation of different loss-factor values in Fig. 1 is very interesting. It shows that for the usual values of load factor, from $F = 0.4$ to $F = 0.8$, the loss factor ranges from $f = 0.11$ to $f = 0.235$, and, from $f = 0.54$ to $f = 0.685$, respectively, if the curves, E and C, are assumed as limits; or from $f = 0.065$ to $f = 0.5$, and from $f = 0.52$ to $f = 0.8$, respectively, if Curves A and B are assumed as limits. This proves that the error in determining the penstock diameter for small load factors can be very high. For $f = 0.4$, for example, the error in Curves C and E equals $\sqrt[6.9]{\frac{0.235}{0.110}} - 1 = 0.116$; and in Curves A and B, $\sqrt[6.9]{\frac{0.40}{0.065}} - 1 = 0.3013$. The error is between 11.6% and 30.13%, thus nullifying the value of the meticulous and laborious determination of the economic diameter.

---

[28] Manuals of Engineering Practice, Am. Soc. C. E., No. 11, p. 6.

The writer considers that it is impossible to give any general factors, such as a loss factor, or any limiting values for the exact computation of penstocks. Every region or district has its own characteristics which must be considered in each case separately. This can be determined, correctly and quickly, in the following manner.

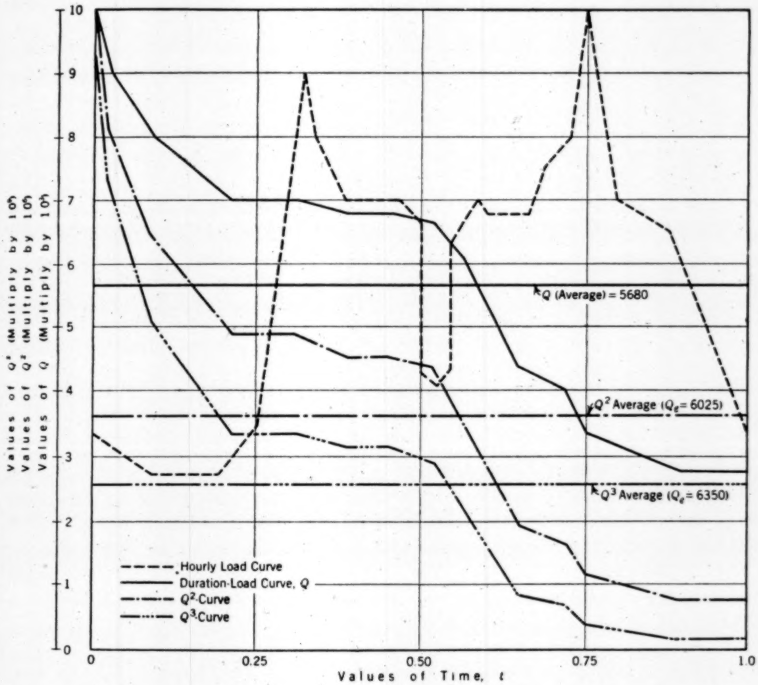

FIG. 4.—COMPUTATION OF EQUIVALENT DISCHARGES

A load-duration curve is usually computed in any case. For different points on such a curve compute the values of Q^2 and Q^3, as shown in Fig. 4. The second and third roots, respectively, the averages of these values, in Equation (62), will give the correct equivalent values of Q_e for the computation of the economical diameter of the penstock. These equivalent discharges are the correct values for the consumption region. This simple computation eliminates any inexactness resulting from values taken from the curves in Fig. 1.

Limitation of Discussion.—It should be noted that this discussion is limited to penstocks, in which the water pressure is great enough, because Equation (6) is correct only if the pressure in the top and in the bottom of the ring can be assumed to be equal (see Fig. 5(*a*)). For penstocks under low and medium pressure ($H < 200$ ft), the ring formula cannot be applied (see Fig. 5(*b*)). Therefore, Item No. 2, in Table 3, has been computed incorrectly. This is also true in the case of Item No. 3.

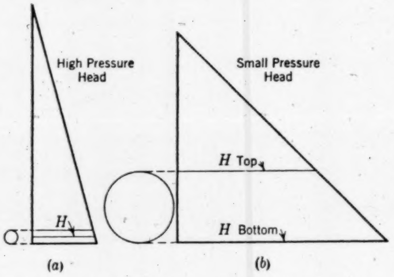

FIG. 5.—PRESSURE DISTRIBUTION IN PIPE

Furthermore, the present analysis is based only on hydrostatic pressure. In most cases the stresses due to the bending of the pipe between the supports must be considered and Equations (6), (7), (9), (10), (11), (20), (22), (23*d*), (27), (28), (30), and (33) must be changed accordingly.

Validity of Equation (6).—In the present analysis Equation (6) is valid only for pipes in which the relation of the thickness of steel to the diameter is very small, $\frac{t}{D} < \frac{1}{20}$. In all other cases the equations must be changed accordingly. Professor Ludin proposes using the outside diameter instead of the inside diameter in Equations (11) and (44).

Other Limiting Factors.—Finally, the diameter is limited due to the fact that, in cases of large discharges, two or more penstock lines are used. This effect can be considered by reducing the equivalent discharge by the number of pipes. Diameters of 21.30 ft and 17.42 ft (Items Nos. 3 and 6, Table 3) seem to be too large to be advantageous in actual operation. Fig. 2 demonstrates that for small heads and large discharges, the values of the penstock diameters do not change very much. For example, when $H = 100$ ft and $Q = 5\,000$ cu ft per sec, $D = 25.50$ ft; and for the same head and $Q = 6\,000$ cu ft per sec, $D = 26.60$ ft. In other words, a change of 20% in the rate of flow, changes the diameter only 7.6 per cent. This is clear because of the unimportance of friction losses in the computation of large diameters. Furthermore, the factors discussed herein under the heading, "Limitation of Discussion," should be considered as well. Thus, the values given in Items Nos. 3 and 6, Table 3, should be considered as being not exactly correct. The present analysis, therefore, is limited to penstocks of small and medium diameters (not greater than 12.0 ft), and great heights ($H > 300$ ft).

It seems to be very questionable whether the diameters of penstocks situated immediately down stream from the dam can be found by the analysis suggested in this paper. Furthermore, the construction of a nomogram has two advantages: (1) It permits finding the maximum heads for given discharges and given diameters, for the standard sizes; and (2), once it has been computed no further calculation is required. Fig. 2 can replace all the calculations in ordinary cases of penstocks.

For assistance in reading this discussion and encouraging the writer in his efforts, acknowledgment is freely given to R. W. Powell, M. Am. Soc. C. E., and Mr. D. C. Williams, of Ohio State University.

F. KNAPP,[29] ESQ. (by letter).—It is a well known fact that, in most cases, penstocks for high-head plants have diameters decreasing toward the power house. The authors do not state the range of applicability of their own formula, nor do they mention the limit of application of the usual orthodox design with varying diameters.

The analysis submitted by the authors, resulting in a penstock with a constant diameter, is applicable as long as: (1) The cost of the penstock per ton is constant irrespective of the variation of the diameters; and (2) the top section of the penstock does not require a minimum thickness, imposed either for practical reasons or in virtue of danger of collapse.

Let ΔL be a short length of the pipe, with an internal diameter, D, under the total head, H. With a circumferential stress, s, the thickness of the shell (using the simple cylinder formula) becomes:

$$t = \frac{0.434\, H\, D \times 12}{2\, s} \qquad \text{.....................} (63)$$

Now, assume that the pipe forms a cone with the small angle, $2\,\alpha$, at the summit. Using the symbol, D_a, to denote average diameter, the weight of the pipe with the length, ΔL, is:

$$W = w\, D_a\, \pi \frac{\Delta L\, t}{\cos \alpha \times 12} = \frac{w\, D^2_a\, \pi\, H \times \Delta L \times 0.434 \times 12}{2\, s \cos \alpha \times 12} = \frac{\text{constant}}{\cos \alpha} \quad .. (64)$$

in which w = the weight of steel, in pounds per cubic foot (= 490).

The loss of head, due to friction, is given by:

$$h_f \doteq K \frac{\Delta L}{D_a} \frac{V^2}{2\, g} = K_1 \frac{Q^2}{D^5_a} \Delta L \qquad \text{...............} (65)$$

Angle α does not appear in Equation (65) and this means that the loss of head in the two cases (constant diameter and decreasing diameter) is the same. However, the weight of the pipe, according to Equation (64), becomes a minimum when $\cos \alpha = 1$. The diameter, therefore, should be constant.

The foregoing two assumptions are the basic requirements for the applicability of the authors' formula. However, in cases where the thickness of the top section of the penstock is not determined by stress conditions, or when a special type of pipe is used in the bottom section (such as forged or banded pipe) which has the effect of increasing unit cost sharply, then the diameters of the penstock, to be the most economical ones, should be stepped.

---

[29] Licensed Engr., São Paulo, Brazil.

Certain high-head penstocks are designed on the basis of accidental surge conditions. In such cases, the determination of the design head, including water-hammer, needs to include the influence of variations of diameter and thickness.[30]

A paper on high-head penstock design presented in 1933 contains a proposal to increase the diameters toward the power house,[31] in order to avoid the considerably increased surge in the second positive period, which is sometimes as great as 200% of the primary surge, due to reflections at changes of diameters and thicknesses. This proposal, fortunately, has not been adopted, as it is based on an incomplete study. For penstocks with decreasing diameters and which are designed to take extreme surge conditions into account, the writer has shown that the "reflection-times" of the various diameter sections should be exactly equal and, furthermore, that the "transmission-factors" for the surge wave should be nearly equal.[32] These two requirements (actually incorporated in the design of three important high-head penstocks), together with the consideration of the influence of head losses, have the economic advantage of reducing the absolute maximum surge to values either equal to, or only slightly greater than, the primary surge.

For such a penstock design with limitations, imposed by surge conditions, it becomes almost impossible to determine the best diameters by analytic methods. For the aforementioned penstocks, the writer developed a direct graphical method without the use of "cut and try" methods, which permits investigating all influencing factors with a negligible amount of labor.

The authors based their analysis on minimum total annual cost. This assumption corresponds to a situation in which funds for investment in the project are limited only by the necessity of making the project as attractive as possible. From an economic point of view, it would be justifiable to go beyond the point of minimum total yearly cost to a point corresponding to the case where funds for investment are unlimited, provided the return on each dollar invested will equal or exceed a fixed minimum.

Most penstocks are designed on the basis of "output." In certain cases, it becomes necessary to base the analysis on "capacity" and according to the prevailing conditions, both output and capacity must be taken into account.

It appears from the foregoing that too much refinement of analytical methods is not warranted, and that all such computations should be used, combined with sound judgment, to arrive at the best solution.

[32] "Simple Graphical Solution for Pressure Rise in Pipes and Pump Discharge Lines," by R. W. Angus, *Proceedings*, The Eng. Inst. of Canada, 1935, Vol. 18, p. 72; discussion by F. Knapp, p. 267.

Ralph W. Powell,[33] M. Am. Soc. C. E. (by letter).—In their "Synopsis" the authors state that their formulas differ from those heretofore published in three particulars. The writer believes that Items (*b*) and (*c*) constitute worth while improvements, although in the case of Item (*c*) it may be noted that where a hydro-electric plant is operated at low load factor, it is usually to supply "peak power" which would be more valuable, so that the product, $f\,b$, in Equation (11), may be fairly constant after all. However the authors' form would be useful if it were adapted (as it easily could be) to the case of the economic diameter of a pipe through which water is to be pumped. If the use were not continuous, the economic diameter would certainly be somewhat less than for continuous operation at capacity.

H. L. Doolittle,[18] M. Am. Soc. C. E., as well as William P. Creager and Joel D. Justin, Members, Am. Soc. C. E. (who were cited by the authors), brought the load factor into the problem. Mr. Doolittle stated very clearly that the annual cost of the lost power will vary as the average of the cubes of the various flows; he drew a duration curve and another curve obtained by cubing the ordinates of the duration curve; and showed that f is the cube root of the ratio of the average ordinate of the latter curve to its maximum ordinate. It seems that this is the only satisfactory way to obtain the value, f, and that it cannot be obtained from F alone. There are many possible duration curves, all giving the same power factor, which will yield quite different values of f. For instance, suppose a straight line varying from maximum to zero, and a curve the ordinates of which vary as one plus the cosine of an angle from 0 to 180 degrees. Both give $F = 0.500$, but the first gives $f = 0.250$ and the second, $f = 0.125$ (if 3 is used as the exponent of Q. If 2.9 is used, as the authors have done, $f = 0.256$ and 0.134, respectively. These correspond to Curves *D* and *B* of Fig. 1).

Returning now to the consideration of Item (*a*), the writer questions whether the Scobey formula is the best on which to base the theory of economic design, and whether it would not be better to assume that friction losses vary as the square of the velocity. This statement represents a change in opinion, because in 1927 the writer proposed a formula[34] based on the Hazen-Williams formula for pipe friction. This gave an exponent of 0.146 which is equivalent to the 6.85 root in Equation (11) as compared to 6.9 given by the authors, and 7 by the simpler theory now proposed. This was before Mr. Scobey published his formula. Four or five years later, the writer would undoubtedly have followed Mr. Scobey, as the authors have done; but in the last few years additional light has been thrown on frictional losses at high Reynolds' numbers by J. Nikuradse,[35]

[35] "Strömungsgesetze in rauhen Röhren", von J. Nikuradse, Verein Deutscher Ingenieur, *Forschungsheft*, No. 361, 1933.

V. L. Streeter, Jun. Am. Soc. C. E.,[36] H. Schlichting,[37] and others. These data have been summarized in English by Mr. Streeter and Hunter Rouse, Assoc. M. Am. Soc. C. E.[38] Fig. 2 in Mr. Streeter's paper, and Fig. 10 in that of Mr. Rouse, give Nikuradse's results. The lowest curve, representing a roughness of $\frac{1}{507}$ of the radius of the pipe, would seem to be suitable for most steel penstocks. At any rate plotting Weisbach's f from Mr. Scobey's original data against the Reynolds' number, it seems to agree with this curve as well as with his own equation. Attention is especially called to Runs 65, 66 and 312 of his paper[4] which show a definite tendency of Weisbach's f to increase in the region at a Reynolds' number of approximately 1 000 000, just as it does in Nikuradse's lower curve. (Of course, various types of riveting, age of pipe, etc., will give a series of curves, some lower and some higher, with their minimum points at somewhat different Reynolds' numbers.)

If Nikuradse is correct (and Streeter and Schlichting have confirmed his work), the correct exponent of the velocity to give the friction head in a typical large steel pipe would vary from 1.75 for Reynolds' numbers between about 4 000 and 50 000; then it would increase to 2.00 at about 200 000, and to 2.10 at about 300 000; decrease to 2.00 at about 1 000 000; and remain constant for higher values. It would seem, therefore, that for the Reynolds' numbers usually encountered in a penstock, 2 would be as good a value to use as any. This would change Equation (11) to the seventh root, Equations (32) and (33) to the sixth root, and would greatly simplify the intermediate equations.

It should perhaps be re-emphasized that Equations (11) to (27) apply to high heads where the necessary thickness varies directly as the product of the head and diameter; and Equations (32) and (33) to the almost equally important case of low head in which the thickness of the shell is independent of both the head and the diameter. The writer must confess that he has never studied thoroughly the design of large pipe lines,[39] but he raises the question as to whether there is not a third case to be considered—that in which the maximum shear in the pipe shell, considered as a beam, will govern the thickness so that it will be independent of the head but dependent upon the diameter.

The writer does not wish these remarks to be taken as adverse criticism of the paper as a whole, because he considers it a valuable piece of work done in a careful and thorough manner. He is particularly sorry that the senior author cannot participate in the discussion of the points herein raised.[1] Many years ago he had the privilege of working for some weeks in the same room as Mr. Voetsch and under his immediate supervision. No young engineer could ask for a more kindly chief, or one with wider experience or sounder engineering judgment.

H. K. Barrows,[40] M. Am. Soc. C. E. (by letter).—The formulas developed by the authors are of interest, and are novel in certain respects. The use of the Scobey formula for friction head loss, involving, as it does, special exponential values for V and D other than the square and first powers, respectively, causes Equation (11) to make the economic diameter vary as the $\sqrt[6.9]{\ }$, whereas if the simpler common formula for friction head losses,

$$h_f = \frac{K'}{D} \times \frac{V}{2\,g} \quad \text{.........................(66)}$$

is used, this becomes $\sqrt[7]{\ }$. It seems questionable whether the use of the Scobey formula is preferable under the circumstances.

Furthermore, the introduction of entrance losses, bend losses, etc., commonly of minor effect, could well be avoided, for the sake of simplicity, without appreciable effect upon results. The use of a loss factor to take account of load factor is logical and warrants further study and determinations of such factors. The writer has found the formula,[41]

$$D = 0.215 \sqrt[7]{\frac{K'\, b'\, Q^3_a\, s}{a\, r\, H}} \quad \text{..................(67)}$$

for steel pipes, convenient for obtaining a quick approximation of the best penstock size as a basis for further detailed study made by assuming different sizes, determining annual cost (of pipe plus value of power lost), and plotting total yearly cost against diameter.

In Equation (67), in addition to the notation of the paper: b' = the value of power, in dollars per theoretical horse-power per year; Q_a = average discharge, or maximum discharge, times a capacity factor; s = unit stress value of steel; and K' = friction factor in the formula,

$$h_f = \frac{K'\, L\, V^2}{2\, D\, g} \quad \text{.........................(68)}$$

The use of the average discharge applies fairly closely where individual penstock lines are considered, if wheel units are operated by number and gate for best results. For a long single penstock the correct discharge would be more nearly the maximum discharge times the square of the capacity factor.

---

[40] Prof., Hydr. Eng., Mass. Inst. Tech., and Cons. Engr., Boston, Mass.

[41] "Water Power Engineering", by H. K. Barrows, 1934 Edition, p. 357.

Similar formulas have been deduced for concrete and wood-stave penstocks, the one for concrete being as follows:[42]

$$D = 0.215 \sqrt[7]{\frac{K'\, b'\, Q^3{}_a}{r\left(0.0000290\, a_c + 0.384\, p\, a_s + \frac{a_s\, H}{s_s}\right)}} \quad \ldots\ldots (69)$$

in which, in addition to the notation of the paper: a_c = cost of concrete, in dollars per cubic yard; p = ratio of cross-sectional steel area of longitudinal steel to that of concrete in the same plane; a_s = cost of steel reinforcement, in dollars per pound; and, s_s = allowable stress in hoop steel, in pounds per square inch. The quantity in parenthesis includes the effect of concrete cost, longitudinal steel, and hoop steel, respectively.

For wood-stave penstocks:

$$D = 0.215 \sqrt[7]{\frac{K'\, b'\, Q^3{}_a\, s}{r\, H\, (a_b + 0.000016\, a_w\, s)}} \quad \ldots\ldots\ldots\ldots (70)$$

in which, a_b = cost of steel bands, in dollars per pound; and a_w = cost of wood staves, in dollars per board-foot.

Equation (67) for steel pipes is simple enough to be useful; but Equations (69) and (70) are somewhat long and involved in use, and the writer prefers, in general, to determine the best size of penstock by curves rather than by formula, as this enables all special items of cost, other other than of pipe alone, to be included.

ROBERT W. ANGUS,[43] ESQ. (by letter).—The method of determining the economic diameter of penstocks has been presented in an interesting and valuable manner in this paper, and the authors have expressed the results in convenient formulas.

In the investigation the head, H, is defined as "the average head, on the penstock, including water-hammer effect, in feet", but the water-hammer itself may have an important influence on the size of the pipe, and the pressure rise due to this effect may be so large as to make Equation (6) inaccurate. A few years ago the writer was making some studies with a model pipe line having a glass surge tank. The top of this tank was open, was above the forebay level, and was tested and found to be amply strong for pressures produced by the static head in it. On several occasions, however, the glass surge tank was broken by a quick closure of the turbine gate, although no water came over the top of the tank, and a carefully made indicator showed pressures at its base much in excess of those due to the height of the water column.

Of course, it is well known that under favorable conditions, the water-hammer pressure rise, in feet, may be about 100 times the velocity dissipated, and also that these bad conditions may readily occur in a long penstock or pipe. For example, if a pipe is 6 000 ft long, the foregoing pressure rise will occur for valve closure requiring a period of 4 sec, or less, a length of time easily within the operation range of a governor; and if the pipe is under a low head of perhaps 100 ft and has its velocity of, say, 4 ft per sec dissipated, the pressure from the resulting water-hammer will be five times the normal pressure.

---

[42] "Water Power Engineering", by H. K. Barrows, 1934 Edition, p. 358.

[43] Prof. of Mech. Eng., Univ. of Toronto, Toronto, Ont., Canada.

Recently, a case came to the writer's attention, in which two pipes ran parallel to each other from the side of a reservoir and were joined at their lower ends by a **U**-bend. Each pipe had a valve near the reservoir and the valves were under a static head of 66 ft, one valve being open and the other closed at the time. Each pipe also had a turbine connected near its lower end, one of which was shut down, and the other running. The operating turbine was then stopped by a quick, not "sudden", closure of the gates (that is, the closing time exceeded the total time of the pressure wave), but the resulting pressure rise was sufficient to break the closed valve that was near the reservoir. An examination suggested that the resulting pressure was more than twice the static head of 66 ft.

It would appear desirable and necessary, therefore, to include the water-hammer effect in a much more exact manner than by merely taking its average value. In the Symposium on Water Hammer sponsored by the Society, among others,[24] A. W. K. Billings, M. Am. Soc. C. E., has shown that the study of water-hammer modifies the design of the pipe line greatly. In view of the fact that the pressure rise due to this cause may be so easily arrived at graphically,[44] even in fairly complicated systems, it would seem that it should be included in any economic study, although the mathematical expressions for it would be difficult to include in ordinary equations.

M. H. Fresen,[45] Assoc. M. Am. Soc. C. E. (by letter).—The discussions which have been presented, contain much valuable information and constructive criticism.

Economic Diameter Using Weisbach Formula for Friction Loss.—Mr. Monroe and Professors Powell and Barrows prefer to use the Weisbach (also sometimes called Darcy or Chezy) formula for head lost in friction in conduits. Since the paper was prepared, friction factors (Table 6) for use in the Weisbach formula have been made available. For this reason Equations (75) and (76) have been derived.

Using the Weisbach formula for friction head loss (Equation (68) quoted by Professor Barrows), the annual cost of the lost power in a penstock of diameter, D, may be expressed similarly to Equation (5) as:

$$E_f = \frac{18.71\,K'\,L_f\,Q^3\,e\,f\,b}{D^5} \qquad \text{.................... (71)}$$

in which K' equals the friction loss factor, f, in the Weisbach formula.

Inst. of Canada, February, 1935; also, "Water-Hammer in Pipes, Including Those Supplied by Centrifugal Pumps; Graphical Treatment", by Robert W. Angus, *Proceedings*, Inst. of Mech. Engrs., 1937.

[45] Associate Engr., U. S. Bureau of Reclamation, Denver, Colo.

The first derivative of Equation (71) with respect to D is:

$$\frac{dE_f}{dD} = -\frac{93.54\ K'\ L_f\ Q^3\ e\ f\ b}{D^6} \qquad (72)$$

In Equation (72) let $93.54\ K'\ L_f\ Q^3 = G'$, which substituted for G in Equation (24) yields,

$$B = \frac{G'\ J}{D^x} + \frac{M\ J}{D^y} \qquad (73)$$

in which M, J, and B have the values given by Equations (23*b*), (23*c*), and (23*d*), respectively. Letting $x = y = 7$, Equation (73) becomes:

$$D = \sqrt[7]{\frac{J\ (G' + M)}{B}} \qquad (74)$$

approximately, or in terms of the fundamental factors involved, the economic diameter considering the head, H, is:

$$D = \sqrt[7]{\frac{e\ f\ b\ (93.54\ K'\ L_f + 74.83\ K_T)\ Q^3\ s_g\ e_j}{668\ H\ a\ r\ L_p\ (1 + i)}} \qquad (75)$$

which corresponds to Professor Barrow's Equation (67), except that the notation of the paper is used. For greater accuracy, Equation (75) (with $x = 7$ and $y = 6$) can be solved for D by a trial-and-error method.

Considering the shell thickness, t, the following equation is derived similarly to Equation (75):

$$D = \sqrt[6]{\frac{e\ f\ b\ (93.54\ K'\ L_f + 74.83\ K_T)\ Q^3}{128.3\ t\ a\ r\ L_p\ (1 + i)}} \qquad (76)$$

approximately. Equation (76) corresponds to Equation (33) of the paper with the same notation, and is similar to one given by Professor Barrows.[41] For greater accuracy, Equation (31) (with G' substituted for G, and $x = 7$ and $y = 6$) can be solved for D by a trial-and-error method.

Based on a study reported in 1936,[46] selected average friction factors (as read from a chart) for use in the Weisbach formula, Equation (68), are given in Table 6, Columns (3) and (4), corresponding to the recommended equations:

---

[46] "Friction Coefficients of Continuous Interior and Riveted Steel Pipes," by M. B. Karelitz and F. M. Watkins, *Technical Memorandum No. 521*, U. S. Bureau of Reclamation, Denver, Colo., May 14, 1936.

$$K' = 0.0043 + \frac{0.160}{R_n^{0.165}} \qquad (77)$$

for full-riveted pipe; and,

$$K' = 0.0043 + \frac{0.254}{R_n^{0.23}} \qquad (78)$$

for continuous interior pipe. The values in Column (2), Table 6, are based on Reynolds' number,

$$R_n = \frac{V\,D}{\nu} \qquad (79)$$

in which ν = the kinematic viscosity of the fluid. For water at 15° C (59°F), $\nu = 1.23 \times 10^{-5}$ sq ft per sec.

Nomogram for Solution of Economic Diameter.—The nomogram, Fig. 2, presented by Mr. Lewin for solving Equations (47), (48), or (49) for the economic diameter, D, directly, constitutes a valuable addition to the paper. To use Fig. 2, the maximum discharge, Q, and the head, H, for shell thickness, must be known. Since it is probable that for different projects the load factor, F, the shape of the load curve, and the corresponding value of the loss factor, f, will vary more widely than the other factors in Equations (11) or (27), the writer prefers to use Equation (48), Fig. 2, which includes the loss factor. The scale for Equation (48), Fig. 2, is such that the diameter read from it is that for unity load factor and unity loss factor. For a smaller load factor and loss factor, the diameter may be read from Fig. 2 (scale for Equation (48)), and corrected by the ratios given in Table 1, Columns (1) and (2). Similarly, Fig. 2 and Table 1 (preferably plotted in logarithmic curve form) may be used to estimate the diameters for assumptions other than those on which Equation (48) is based. It should be noted that Fig. 2 cannot be used to determine the diameter, D, when the head, H, and allowable stress, s_g, give a smaller penstock shell thickness than the minimum thickness permitted by the specifications being followed in the design. For such cases, Equation (33) should be used.

Economic Diameters, in Terms of Head, and Shell Thickness.—For exactly corresponding assumptions, the economic diameter of a steel penstock in terms of the head, H, is about 11% less than the economic diameter obtained when the shell thickness, t, corresponding to H from Equation (6) is used. At first thought this may appear to be inconsistent and incorrect. Fig. 6 has been prepared to show that such results are correct, and will be obtained whether the economic diameters are found from diameter-total annual cost curves similar to Fig. 6, or from solving Equations (27) and (33).

Fig. 6 is based on the following assumptions: $Q = 1\,000$ cu ft per sec; $K_s = 0.34$; $e = 0.85$; $f = 0.20$ (corresponding approximately to a load factor, F, of about 50%); $b = \$0.003$ per kw-hr; $s_g = 15\,000$ lb per sq in.; $e_j = 0.80$; $a = \$0.11$ per lb; $r = 0.07$; and $i = 0.15$. In this example, the following results are obtained: (*a*) From Fig. 6, Curve E, for a head, H, of 100 ft, the economic diameter is found to be 10.36 ft; (*b*) from Equation (6), the thickness of shell corresponding to a head of 100 ft is $t = 0.225$ in.; (*c*) from Fig. 6, Curve D, for a thickness, t, of 0.225 in., the economic diameter is found to be 11.66 ft; (*d*) substituting the foregoing assumed values in Equation (27), and solving, $D = 10.36$ ft for a head of 100 ft, which agrees with Item (*a*); (*e*) similarly, solving Equation (33), $D = 11.66$ ft for a shell thickness of 0.225 in., which agrees with Item (*c*); (*f*) the ratio of $\frac{\text{Item } (a)}{\text{Item } (c)} = \frac{10.36}{11.66} = 0.889$ (or, in general, the economic diameter of a penstock in terms of head is about 11% less than the economic diameter obtained when the corresponding shell thickness is used); and (*g*) the result of Item (*f*) may also be verified algebraically by a study of Equations (6), (27), and (33), and reference to Table 1.

For corresponding assumptions the results obtained, using the equations, are identical with those determined from a detailed analysis. For all ordinary problems the writer believes an appreciable saving of time will result from using the equations of the paper, compared to a detailed analysis.

Miscellaneous.—Mr. Lewin states that the analysis of the paper is "limited to uniform (that is, horizontal) penstocks." He also questions "whether the diameters of penstocks situated immediately down stream from the dam can be found by the analyses suggested in the paper." The writer assumes that Mr. Lewin refers to Equations (11) and (27) for computing D in terms of the head, for a penstock line of constant diameter. Neither of Mr. Lewin's statements applies as long as the following conditions are fulfilled: (*a*) The cost of the penstock per pound is constant irrespective of the variation of the diameters; (*b*) the top section of the penstock does not require a minimum thickness, imposed either for practical reasons or in virtue of danger of collapse; and (*c*) the average weighted head used in the equations is a true numerical function of the weight of the steel (and, therefore, of the cost) for the penstock, profile, and water-hammer conditions under consideration. Conditions (*a*) and (*b*) are limitations explained by Mr. Knapp.

Equations (51*a*) to (61), inclusive, given by Mr. Lewin, are interesting, but the writer doubts whether the average engineer would have the patience to attempt to apply them. The writer believes it would be more practicable to use Equation (33), applying the method suggested in the paragraph immediately following Equation (33).

Messrs. Santos and Knapp, and Professor Angus discuss water-hammer as affecting penstock design. In addition to the Footnote References (30, 44) given by them, several recent papers[47, 48] on water-hammer may be of interest to those who wish to pursue this phase of the problem further.

Messrs. Santos and Knapp very properly point out that too much refinement of analytical methods is not warranted, and that all such computations should be used, combined with sound judgment, to arrive at the best solution. The number of significant figures in the numerical constants of the equations in the paper should be reduced to four at the most, probably three being all that are justified.

[47] Papers relating to water-hammer phenomena in pipe lines, by Lorenzo Allievi, R. W. Angus, F. Knapp, R. T. Knapp, J. N. Le Conte, O. Schnyder, E. B. Strowger, and F. M. Wood, *Transactions*, Am. Soc. M. E., November, 1937, Vol. 59, No. 8.

[48] "Water-Hammer Pressures in Compound and Branched Pipes," by R. W. Angus, *Proceedings*, Am. Soc. C. E., January, 1938, pp. 133–169.

Mr. Rudolph mentions an interesting application of the formulas of the paper to a problem involving the present value of a saving in the future. This is a phase of the problem in economics which should receive adequate attention.

As mentioned by Messrs. Bier and Lewin, and by Professor Powell, it should be emphasized that Equations (11) and (27) apply to high heads where the necessary shell thickness varies directly as the product of the head and diameter; and Equation (33) to the equally important case of low head in which the thickness of the shell is independent of the head, and for small penstocks, independent of the diameter.[49]

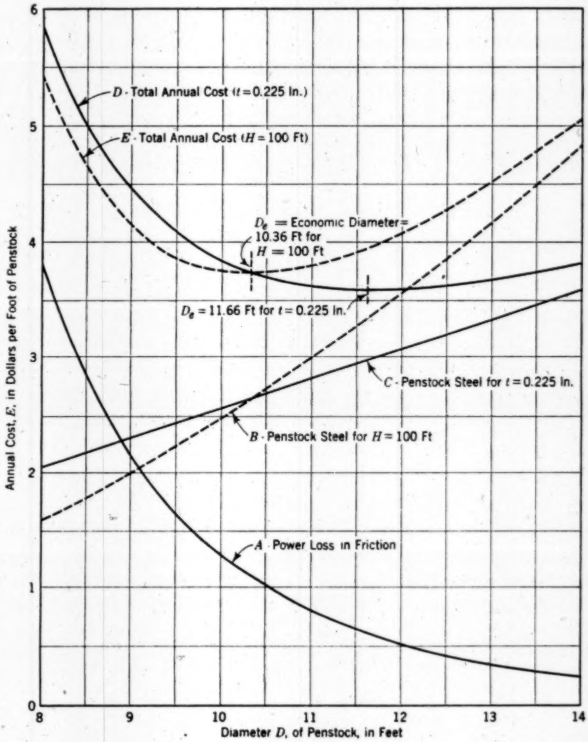

FIG. 6.—ECONOMIC DIAMETER OF STEEL PENSTOCK IN TERMS OF HEAD AND PLATE THICKNESS

Fig. 6 and the example given by Mr. Bier show that the equations of the paper and a detailed analysis give the same results if the same basic data are used throughout.

---

[49] "Penstocks—A Report of the Hydraulic Power Committee," Edison Electric Inst., *Publication No. D15*, December, 1936. This recent report gives much valuable data on design and construction of penstocks. Minimum thickness of steel plates is discussed on p. 5.

Mr. Lewin and Professor Powell comment on the wide range in values of loss factor from Fig. 1 for particular values of load factor. Since no one can predict positively in advance the exact shape and magnitude of a load curve for a projected plant, it is probable that values of loss factor estimated from Fig. 1 are as reliable as those computed by the more accurate method given in the paper, and similar methods mentioned by Mr. Lewin and Professor Powell.

In conclusion, the writer wishes to thank those who have contributed discussions, and hence have added considerably to the value of the paper. The writer appreciates in particular the tribute to Mr. Voetsch[1] expressed by Professor Powell, and shares in his sorrow that the senior author cannot participate in this closing discussion, and enrich it from the wide experience he possessed.

STRESSES AROUND CIRCULAR HOLES IN DAMS AND BUTTRESSES

By I. K. Silverman[1], Jun. Am. Soc. C. E.

With Discussion by Messrs. R. D. Mindlin, Chesley J. Posey, J. H. A. Brahtz, V. L. Fedorov, F. W. Hanna, C. P. Vetter, Fred L. Plummer, and I. K. Silverman.

Synopsis

Cracks that have been observed in dams have sometimes been attributed to the presence of drainage or inspection galleries which are parallel or transverse to the axis of the dam. Some observers have stated that these cracks generally start from the gallery and in some cases travel to both down-stream and up-stream faces, thus dividing the structure into two or more parts. In other cases these cracks are purely local and extend only a short distance from the gallery into the main part of the dam. Both these types of cracks can be observed on the faces of buttresses.

The stresses which occur around these openings are due to volumetric changes arising from shrinkage, temperature, etc., and to water and mass loads. An attempt is made in this paper to analyze the stresses around a circular opening caused by water and mass loads.

Notation.—In the notation introduced herein (see Appendix I) an effort has been made to conform to the American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials[2], compiled by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

General Formulas

Both theory and experiment[3] have shown that, in a large body, the effect of a relatively small opening is a purely local one. The stresses at points that are removed a sufficient distance from the discontinuity are essentially the same as if there were no hole. A case that has been investigated to some

---

Note.—This paper was published in November, 1936, *Proceedings*.

extent is that of a circular hole in a bar subjected to uniform tension. The normal stress, s_{nx}, on Section AA of Fig. 1[4] is given by,

$$s_{nx} = \frac{s}{2}\left(2 + \frac{r^2_h}{\rho^2} + 3\,\frac{r^4_h}{\rho^4}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots(1)$$

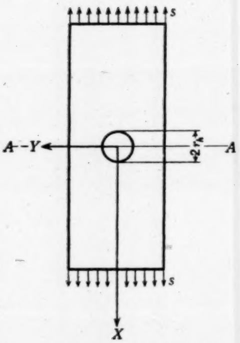

FIG. 1

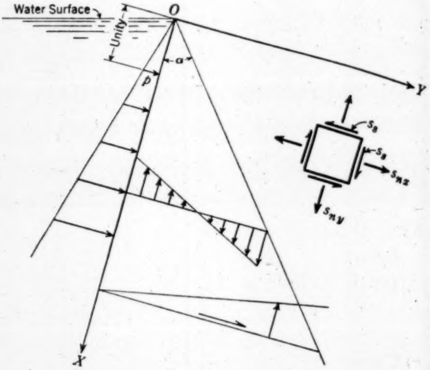

FIG. 2

in which s = the total load divided by the gross area of the bar; r_h = the radius of the hole in the bar; and ρ = radial distance from center of hole. As ρ increases s_{nx} approaches s. In the immediate vicinity of the hole, however, the stresses are larger than those calculated as if no hole existed; and $s_{nx} = 3\,s$ in Equation (1) if $\rho = r_h$.

STRESSES DUE TO WATER LOAD

Although openings in dams or buttresses are not always circular the state of stress around such openings may be examined on the assumption that they are circular. In the analysis which follows the usual assumptions of homogeneity, elastic behavior, and the applicability of Hooke's law, are made. Triangular dams and buttresses subjected to hydrostatic loadings are usually designed on the assumption that the normal stresses, s_n, on a section are distributed linearly (see Fig. 2) and are given by,

$$s_n = \frac{p\,x}{K^2} - 2\,\frac{p\,y}{K^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots(2)$$

in which p = pressure at a unit distance measured from O along the up-stream face (Fig. 2); K = a substitution factor = tan α; α = the angle between the battered faces of a dam; and x and y are variable distances measured in the X- and Y-directions, respectively. The shear stresses, s_s (see Fig. 2), are given by,

$$s_s = -\,\frac{p\,y}{K^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

---

[4] "Theory of Elasticity", by S. Timoshenko, p. 78.

Considered as a two-dimensional problem, the equations of equilibrium of a rectangular particle are:

$$\frac{\partial s_x}{\partial x} + \frac{\partial s_s}{\partial y} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

and,

$$\frac{\partial s_y}{\partial y} + \frac{\partial s_s}{\partial x} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

To preserve geometrical continuity under Hooke's law and to satisfy the equations of equilibrium, the stresses, s_x, s_y, and s_s, are defined as follows:

$$s_x = \frac{\partial^2 F}{\partial y^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

$$s_y = \frac{\partial^2 F}{\partial x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

and,

$$s_s = - \frac{\partial^2 F}{\partial x \, \partial y} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6c)$$

in which, F, the Airy stress function, is given by the following:

$$\frac{\partial^4 F}{\partial x^4} + 2 \frac{\partial^4 F}{\partial x^2 \, \partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \quad \ldots\ldots\ldots\ldots\ldots (7)$$

A solution of Equation (7) that satisfies all boundary conditions for a triangular dam section loaded as shown in Fig. 2 is:

$$F = \frac{p \, x \, y^2}{2 \, K^2} - \frac{p \, y^3}{3 \, K^3} - \frac{p \, x^3}{6} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

from which the stresses by Equation (6) are found to be:

$$s_x = \frac{\partial^2 F}{\partial y^2} = \frac{p \, x}{K^2} - \frac{2 \, p \, y}{K^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9a)$$

$$s_y = \frac{\partial^2 F}{\partial x^2} = - p \, x \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9b)$$

and,

$$s_s = - \frac{\partial^2 F}{\partial x \, \partial y} = - \frac{p \, y}{K^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9c)$$

Transferring the origin of co-ordinates to x_0, y_0 (Fig. 3(a)), and using polar co-ordinates, the stresses acting on a particle bounded by the arcs of two concentric circles and by two radial lines (Fig. 3(b)) are given by:

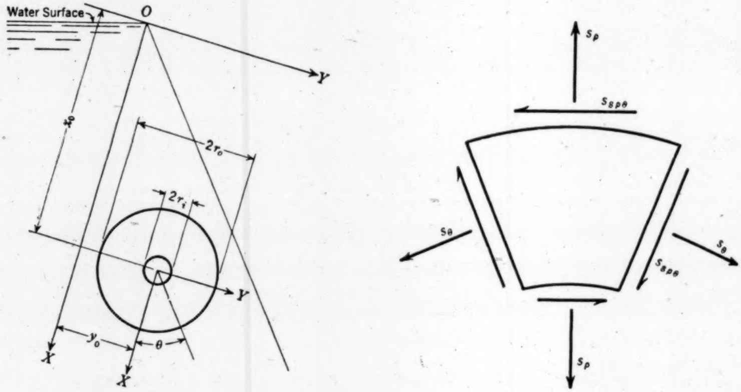
$$\begin{aligned} s_\rho = - \frac{p}{6 \, K^3} \Bigg[& 3 \, \rho \sin \theta + 6 \, K \, y_0 \sin 2 \, \theta + 3 \, \rho \sin 3 \, \theta \\ & + \left(\frac{3 \, \rho K^3}{2} - \frac{3 \, K \, \rho}{2} \right) \cos \theta + \left(6 \, y_0 - 3 \, K \, x_0 - 3 \, K^3 \, x_0 \right) \cos 2 \, \theta \\ & - \left(\frac{3 \, \rho}{2} K^3 + \frac{9 \, \rho}{2} K \right) \cos 3 \, \theta + 3 \, K^3 \, x_0 + 6 \, y_0 - 3 \, K \, x_0 \Bigg] \ldots (10) \end{aligned}$$

$$s_s = \frac{p}{6\,K^3}\left[\left(\frac{3\,\rho}{2}\;K - \frac{3\,\rho}{2}\;K^3\right)\sin\theta + \left(6\,y_0 - 3\,K^3\,x_0 - 3\,K\,x_0\right)\sin 2\,\theta\right.$$
$$\left. - \left(\frac{9\,K\;\rho}{2} + \frac{3\,K^3\,\rho}{2}\right)\sin 3\,\theta + 3\,\rho\cos\theta - 6\,K\,y_0\cos 2\,\theta - 3\,\rho\cos 3\,\theta\right]. \quad (11)$$

and,

$$s_\theta = -\,\frac{p}{6\,K^3}\left[6\,K^3\left(\rho\cos^3\theta + x_0\cos^2\theta\right) + 12\left(\rho\sin^3\theta + y_0\sin^2\theta\right)\right.$$
$$\left. - \,6\,K\left(3\,\rho\sin^2\theta\cos\theta + 2\,y_0\sin\theta\cos\theta + x_0\sin^2\theta\right)\right] \ldots\ldots (12)$$

in which ρ and θ are the polar co-ordinates.



(a) (b)

FIG. 3

If a solid disk of radius, $\rho = r_o$ (outer radius), is considered to be cut from the triangular section, the stresses acting on its boundary are obtained by inserting $\rho = r_o$ in Equations (10) and (11). If, now, $\rho = r_i$ (inner radius) is the radius of the circular opening, then in accordance with the assumption that the stresses on the boundary, $\rho = r_o$, are the same as if no hole existed, the problem reduces to the study of an annular closed ring subjected to the following stresses:

$$s^{\rho o} = A_0 + \sum_{n=1}^{n=3} A_n \cos n\,\theta + \sum_{n=1}^{n=3} B_n \sin n\,\theta \;\ldots\ldots\ldots (13a)$$

$$s_{\rho i} = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

$$s_{so} = C_0 + \sum_{n=1}^{n=3} C_n \cos n\,\theta + \sum_{n=1}^{n=3} D_n \sin n\,\theta \ldots\ldots\ldots (13c)$$

and,

$$s_{si} = 0 \qquad \text{(13}d\text{)}$$

in which $s_{\rho o}$ = the radial stress for a radius, r_o; $s_{\rho i}$ = the radial stress for a radius, r_i; s_{so} = the shear stress for a radius, r_o; s_{si} = the shear stress for a radius, r_i; and A_o, C_o, A_n, B_n, C_n, and D_n are defined as:

$$A_o = -\frac{p}{2\,K^3}\,(K^3\,x_o + 2\,y_o - K\,x_o) \qquad \text{(14}a\text{)}$$

$$A_1 = -\frac{p\,r_o}{4\,K^3}\,(K^3 - K) = D_1 \qquad \text{(14}b\text{)}$$

$$A_2 = -\frac{p}{2\,K^3}\,(2\,y_o - K\,x_o - K^3\,x_o) = -D_2 \qquad \text{(14}c\text{)}$$

$$A_3 = \frac{p\,r_o}{4\,K^3}\,(K^3 + 3\,K) = -D_3 \qquad \text{(14}d\text{)}$$

$$B_1 = -\frac{p\,r_o}{2\,K^3} = B_3 = C_3 = -C_1 \qquad \text{(14}e\text{)}$$

$$B_2 = -\frac{p\,y_o}{K^3} = C_2 \qquad \text{(14}f\text{)}$$

and,

$$C_o = 0 \qquad \text{(14}g\text{)}$$

The analysis of this annular ring, given in Appendix II, results in the following formulas for the radial, circumferential, and shear stresses in the proximity of the opening:

$$\begin{aligned} s_\rho = {} & A_o\left(1 - \frac{r^2_h}{\rho^2}\right) + r_h\left(M_1\cos\theta + M_2\sin\theta\right)\left(\frac{\rho}{r_h} - \frac{r^3_h}{\rho^3}\right) \\ & - \left(A_2\cos 2\,\theta + B_2\sin 2\,\theta\right)\left(4\,\frac{r^2_h}{\rho^2} - 1 - 3\,\frac{r^4_h}{\rho^4}\right) \\ & - r_h\left(M_3\cos 3\,\theta + M_2\sin 3\,\theta\right)\left(-\frac{\rho}{r_h} + 5\,\frac{r^3_h}{\rho^3} - 4\,\frac{r^5_h}{\rho^5}\right) \qquad \text{(15)} \end{aligned}$$

$$\begin{aligned} s_\theta = {} & A_o\left(1 + \frac{r^2_h}{\rho^2}\right) + r_h\left(M_1\cos\theta + M_2\sin\theta\right)\left(3\,\frac{\rho}{r_h} + \frac{r^3_h}{\rho^3}\right) \\ & - \left(A_2\cos 2\,\theta + B_2\sin 2\,\theta\right)\left(3\,\frac{r^4_h}{\rho^4} + 1\right) \\ & + r_h\left(M_3\cos 3\,\theta + M_2\sin 3\,\theta\right)\left(-\frac{\rho}{r_h} + \frac{r^3_h}{\rho^3} - 4\,\frac{r^5_h}{\rho^5}\right) \qquad \text{(16)} \end{aligned}$$

and,

$$s_s = r_h \left(\frac{\rho}{r_h} - \frac{r^3{}_h}{\rho^3}\right)\left(M_1 \sin\theta - M_2 \cos\theta\right) + \left(A_2 \sin 2\,\theta - B_2 \cos 2\,\theta\right)$$

$$\left(3\,\frac{r^4{}_h}{\rho^4} - 1 - 2\,\frac{r^2{}_h}{\rho^2}\right) + r_h\left(4\,\frac{r^5{}_h}{\rho^5} - \frac{\rho}{r_h} - 3\,\frac{r^3{}_h}{\rho^3}\right)\left(M_3 \sin 3\,\theta - M_2 \cos 3\,\theta\right) . \text{(17)}$$

in which $M_1 = -\frac{p}{4\,K^3}\left(K^3 - K\right)$; $M_2 = -\frac{p}{2\,K^3}$; and, $M_3 = \frac{p}{4\,K^3}\left(K^3 + 3\,K\right)$.

Equations (15), (16), and (17) suffice for the determination of the principal stresses near the opening. The hoop stresses may be determined from Equation (16) using $\rho = r_h$ and results in,

$$s_\theta = 2\,A_0 + 4\,r_h\,(M_1 \cos\theta + M_2 \sin\theta) - 4\,(A_2 \cos 2\,\theta + B_2 \sin 2\,\theta)$$

$$- 4\,r_h\,(M_3 \cos 3\,\theta + M_2 \sin 3\,\theta) \ldots\ldots\ldots\ldots\ldots \text{(18)}$$

STRESSES DUE TO MASS

The equations of equilibrium of a particle (Fig. 3(*b*)) under the action of gravity forces are as follows:

$$\frac{\partial s_\rho}{\partial \rho} + \frac{\partial s_s}{\rho\,\partial\theta} + \frac{s_\rho - s_\theta}{\rho} + c\cos(\theta - \beta) = 0 \ldots\ldots\ldots\ldots \text{(19a)}$$

and,

$$\frac{\partial s_\theta}{\rho\,\partial\theta} + \frac{\partial s_s}{\partial\rho} + \frac{2\,s_s}{\rho} - c\sin(\theta - \beta) = 0 \ldots\ldots\ldots\ldots \text{(19b)}$$

in which c = the weight per unit volume; and β = the angle between the direction of gravity and the X-axis.

If the stresses are now defined by,

$$s_\rho = \frac{\partial^2 F}{\rho^2\,\partial\,\theta^2} + \frac{1}{\rho}\,\frac{\partial F}{\partial\rho} - c\,\rho\cos(\theta - \beta) \ldots\ldots\ldots\ldots \text{(20a)}$$

$$s_\theta = \frac{\partial^2 F}{\partial\rho^2} - c\,\rho\cos(\theta - \beta) \ldots\ldots\ldots\ldots\ldots\ldots \text{(20b)}$$

and,

$$s_s = -\frac{\partial}{\partial\rho}\left(\frac{\partial F}{\rho\,\partial\,\theta}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(20c)}$$

the equations of equlibrium and the compatibility resulting from Hooke's law will be satisfied if F is a solution of Equation (21):

$$\left(\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\,\frac{\partial}{\partial\rho} + \frac{1}{\rho^2}\,\frac{\partial^2}{\partial\theta^2}\right)\left(\frac{\partial^2 F}{\partial\rho^2} + \frac{1}{\rho}\,\frac{\partial F}{\partial\rho} + \frac{1}{\rho^2}\,\frac{\partial^2 F}{\partial\theta^2}\right) = 0 \ldots \text{(21)}$$

It will be found that the Airy function, F, corresponding to mass and satisfying the boundary conditions for a triangular section is given by,

$$F_g = \frac{1}{6}\,[c_1\,x^3 + (c_1\,k_2 + c_2 - 2\,c_2\,k^2_2)\,y^3 + 3\,c_2\,k_2\,x\,y^2] \ldots\ldots \text{(22)}$$

in which, $c_1 = c\cos\beta$; $c_2 = c\sin\beta$; $k_2 = \cot\alpha$ (see Fig. 2). Transferring the origin to x_o, y_o, and using the definitions stated by Equations (20), the stresses are the following:

$$\begin{aligned} s_\rho = \frac{1}{6}\Bigg[&\left\{\frac{3\,\rho\,c_1}{2} + \frac{3\,\rho}{2}\,c_2\,k_2 - 6\,c_1\,\rho\right\}\cos\theta \\ &+\Big\{3\,c_2\,k_2\,x_o + 3\,y_o\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2) - 3\,c_1\,x_o\Big\}\cos 2\,\theta \\ &+\left\{\frac{9\,\rho}{2}\,c_2\,k_2 - \frac{3\,\rho}{2}\,c_1\right\}\cos 3\,\theta + \left\{\frac{3\,\rho}{2}\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2) - 6\,c_2\,\rho\right\}\sin\theta \\ &- 6\,c_2\,k_2\,y_o\sin 2\,\theta + \frac{3\,\rho}{2}\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2)\sin 3\,\theta \\ &+\Big\{3\,y_o\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2) + 3\,c_2\,k_2\,x_o - 3\,c_1\,x_o - 6\,y_o\,c_2\Big\}\Bigg] \ldots \text{(23)} \end{aligned}$$

$$\begin{aligned} s_\theta = \frac{1}{6}\Bigg[&\left\{\frac{9\,\rho}{2}\,c_1 + \frac{9\,\rho}{2}\,c_2\,k_2 - 6\,c_1\,\rho\right\}\cos\theta \\ &+\Big\{3\,c_1\,x_o - 3\,c_2\,k_2\,x_o - 3\,y_o\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2)\Big\}\cos 2\,\theta \\ &+\left\{\frac{3\,\rho}{2}\,c_1 - \frac{9}{2}\,c_2\,k_2\,\rho\right\}\cos 3\,\theta + \left\{\frac{9\,\rho}{2}\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2) - 6\,c_2\,\rho\right\}\sin\theta \\ &+ 6\,c_2\,k_2\,y_o\sin 2\,\theta - \frac{3\,\rho}{2}\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2)\sin 3\,\theta \\ &+\Big\{3\,y_o\,(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2) + 3\,c_2\,k_2\,x_o - 3\,c_1\,x_o - 6\,y_o\,c_2\Big\}\Bigg] \ldots \text{(24)} \end{aligned}$$

and,

$$\begin{aligned} s_s = -\frac{1}{6}\Bigg[&\frac{3\,\rho}{2}\Big(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2\Big)\cos\theta + 6\,y_o\,c_2\,k_2\cos 2\,\theta \\ &-\left\{\frac{3\,\rho}{2}\Big(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2\Big)\right\}\cos 3\,\theta + \left\{\frac{9\,\rho\,c_1}{2} - \frac{3}{2}\,k_2\,c_2\,\rho - 6\,\rho\,c_1\right\}\sin\theta \\ &+\Big\{3\,c_2\,k_2\,x_o + \Big(c_1\,k_2 + c_2 - 2\,c_2\,k^2_2\Big)3\,y_o - 3\,x_o\,c_1\Big\}\sin 2\,\theta \\ &+\left\{\frac{9\,\rho}{2}\,c_2\,k_2 - \frac{3\,\rho}{2}\,c_1\right\}\sin 3\,\theta\Bigg] \ldots\ldots\ldots\ldots\ldots\ldots \text{(25)} \end{aligned}$$

The stresses given in Equations (23), (24), and (25) may be broken into two separate stress systems each of which are compatible and satisfy Equation (21). Let $s_\rho = (s_\rho)_{\mathrm{I}} + (s_\rho)_{\mathrm{II}}$; $s_\theta = (s_\theta)_{\mathrm{I}} + (s_\theta)_{\mathrm{II}}$; and $s_s = (s_s)_{\mathrm{I}} + (s_s)_{\mathrm{II}}$. The stresses defined by the subscript, II, or the stresses in System II, are given by:

$$(s_\rho)_{\mathrm{II}} = - c_1 \rho \cos \theta - c_2 \rho \sin \theta \ldots\ldots\ldots\ldots \tag{26a}$$

$$(s_\theta)_{\mathrm{II}} = - c_1 \rho \cos \theta - c_2 \rho \sin \theta \ldots\ldots\ldots\ldots \tag{26b}$$

and,

$$(s_s)_{\mathrm{II}} = 0 \ldots\ldots\ldots\ldots \tag{26c}$$

The stresses of System I are then determined by: $(s_\rho)_{\mathrm{I}} = s_\rho - (s_\rho)_{\mathrm{II}}$; $(s_\theta)_{\mathrm{I}} = s_\theta - (s_\theta)_{\mathrm{II}}$; and, $(s_s)_{\mathrm{I}} = s_s$.

Stresses Due to System I.—From this system,

$$A_0 = \frac{y_0}{2}\left(c_1 k_2 - 2 c_2 k_2^2 - c_2\right) + \frac{x_0}{2}\left(c_2 k_2 - c_1\right) \ldots\ldots\ldots\ldots \tag{27a}$$

$$A_1 = D_1 = \frac{r_0}{4}\left(c_1 + c_2 k_2\right) \ldots\ldots\ldots\ldots \tag{27b}$$

$$A_2 = - D_2 = \frac{1}{2}\left\{x_0\left(c_2 k_2 - c_1\right) + y_0\left(c_1 k_2 + c_2 - 2 c_2 k_2^2\right)\right\} . \tag{27c}$$

$$A_3 = - D_3 = \frac{r_0}{4}\left(3 c_2 k_2 - c_1\right) \ldots\ldots\ldots\ldots \tag{27d}$$

$$B_1 = - C_1 = \frac{r_0}{4}\left(c_1 k_2 + c_2 - 2 c_2 k_2^2\right) = B_3 = C_3 \ldots\ldots\ldots\ldots \tag{27e}$$

$$B_2 = C_2 = - c_2 k_2 y_0 \ldots\ldots\ldots\ldots \tag{27f}$$

and,

$$C_0 = 0 \ldots\ldots\ldots\ldots \tag{27g}$$

Using Equation (43), Appendix II, the state of stress around the opening due to System I is described by the following:

$$\begin{aligned} s_\rho = {} & A_0\left(1 - \frac{r_h^2}{\rho^2}\right) + \frac{r_h}{4}\left[\left(c_1 + c\, k_2\right)\cos\theta + \left(c_1 k_2 + c_2 - 2 c_2 k_2^2\right)\sin\theta\right] \\ & \times\left(\frac{\rho}{r_h} - \frac{r_h^3}{\rho^3}\right) - \left(A_2 \cos 2\theta + B_2 \sin 2\theta\right)\left(4\frac{r_h^2}{\rho^2} - 1 - 3\frac{r_h^4}{\rho^4}\right) \\ & - \frac{r_h}{4}\left[\left(3 c_2 k_2 - c_1\right)\cos 3\theta + \left(c_1 k_2 + c_2 - 2 c_2 k_2^2\right)\sin 3\theta\right] \\ & \times\left[-\frac{\rho}{r_h} + 5\frac{r_h^3}{\rho^3} - 4\frac{r_h^5}{\rho^5}\right] \ldots\ldots\ldots\ldots \end{aligned} \tag{28}$$

$$s_\theta = A_0\left(1 + \frac{r_h^2}{\rho^2}\right) + \frac{r_h}{4}\left[\left(c_1 + c_2 k_2\right)\cos\theta + \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\sin\theta\right]$$
$$\times\left(3\,\frac{\rho}{r_h} + \frac{r_h^3}{\rho^3}\right) - \left(A_2\cos 2\,\theta + B_2\sin 2\,\theta\right)\left(3\,\frac{r_h^4}{\rho^4} + 1\right)$$
$$+ \frac{r_h}{4}\left[\left(3\,c_2 k_2 - c_1\right)\cos 3\,\theta + \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\sin 3\,\theta\right]$$
$$\times\left(-\frac{\rho}{r_h} + \frac{r_h^3}{\rho^3} - 4\,\frac{r_h^5}{\rho^5}\right) \ldots\ldots\ldots\ldots(29)$$

and,

$$s_s = \frac{r_h}{4}\left[\left(c_1 + c_2 k_2\right)\sin\theta + \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\cos\theta\right]\left(\frac{\rho}{r_h} - \frac{r_h^3}{\rho^3}\right)$$
$$+ \left(A_2\sin 2\,\theta - B_2\cos 2\,\theta\right)\left(3\,\frac{r_h^4}{\rho^4} - 1 - 2\,\frac{r_h^2}{\rho^2}\right)$$
$$+ \frac{r_h}{4}\left[\left(3\,c_2 k_2 - c_1\right)\sin 3\,\theta - \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\cos 3\,\theta\right]$$
$$\times\left[4\,\frac{r_h^5}{\rho^5} - \frac{\rho}{r_h} - 3\,\frac{r_h^3}{\rho^3}\right] \ldots\ldots\ldots\ldots(30)$$

Substituting $\rho = r_h$ in Equation (29) the hoop stresses are:

$$s_\theta = 2\,A_0 + r_h\left[\left(c_1 + c_2 k_2\right)\cos\theta + \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\sin\theta\right]$$
$$- 4\left(A_2\cos 2\,\theta + B_2\sin 2\,\theta\right)$$
$$- r_h\left[\left(3\,c_2 k_2 - c_1\right)\cos 3\,\theta + \left(c_1 k_2 + c_2 - 2\,c_2 k_2^2\right)\sin 3\,\theta\right] \ldots.(31)$$

Hoop Stresses Due to System II.—An investigation of System II shows that these stresses hold the weight of a solid disk of radius r_o, in equilibrium, whereas the stresses of System I give a zero resultant on the circumference, $\rho = r_o$. Consider an annular disk of the outer radius, r_o, and the inner radius, r_i, subjected to gravity forces. If all the stresses on the radius, r_i are zero, the resultant of all the forces on the radius, r_o, must be equal to the weight of the disk. If System II is to be applied to an annular disk, c must be made to equal to:

$$c = -\,c\left(\frac{r_i^2}{r_o^2} - 1\right) \ldots\ldots\ldots\ldots(32)$$

resulting in a modified System II given by $(s_r)_{\text{II}} = c\left(\frac{r_i^2}{r_o^2} - 1\right)\rho\cos\theta'$; $(s_\theta)_{\text{II}} = c\left(\frac{r_i^2}{r_o^2} - 1\right)\rho\cos\theta'$; $(s_s)_{\text{II}} = 0$; and $\theta' = \theta - \beta$.

An Airy function, F, may be written for this system:

$$F = \tfrac{1}{2}\, c\, r_i^2\, \rho\, \theta \sin \theta \ldots\ldots (33)$$

From Equation (20) it follows that,

$$s_\rho = c \left(\frac{r_i^2}{\rho} - \rho \right) \cos \theta \ldots\ldots (34a)$$

$$s_\theta = -\, c\, \rho \cos \theta \ldots\ldots (34b)$$

and,

$$s_s = 0 \ldots\ldots (34c)$$

For $\rho = r_i$, $s_\rho = s_s = 0$; and, for $\rho = r_o$, $s_\rho = c \left(\frac{r_i^2}{r_o} - r_o \right) \cos \theta$; and, $s_s = 0$.

The hoop stresses due to System II are $s_\theta = -\, c\, r_h \cos \theta$. These stresses must be added to those of System I to describe the complete state of stress due to mass.

Application.—The foregoing equations will be applied to the determination of the stresses around a circular hole in a buttress of a hollow type dam with the following design characteristics:

Clear spacing between buttresses, in feet	55
Average thickness of buttress, in feet	5
Up-stream slope of buttress	0.9
Down-stream slope of buttress	0.36
Height of dam, h, in feet	200
Radius of circular opening, $0.02\,h$, in feet	4
Weight of water, in pounds per cubic foot	62.5
Weight of concrete, c, in pounds per cubic foot	150

The location of the center of the opening is given by $x_0 = 0.5h$, and $y_0 = 0.2h$. From the spacing, thickness, and up-stream slope of the buttress, $p = \frac{(62.5)\,(55 + 5)\,(\sin 48^\circ)}{5} = 556$ lb per sq. ft.; and $c = p \times \frac{150}{556} = 0.27\, p$. It follows that: $K = \tan \alpha = 1.864$; $K_2 = \cot \alpha = 0.5365$; and, $\beta = 42$ degrees.

Stresses Due to Water Load.—Using Equations (14):

$$A_0 = -\, 0.2089\, p\, h \qquad M_1 = -\, 0.1780\, p$$
$$A_2 = +\, 0.29\, p\, h \qquad M_2 = -\, 0.07721\, p$$
$$B_2 = -\, 0.05757\, p\, h \qquad M_3 = +\, 0.4657\, p$$

Substituting in Equation (18) the "hoop stresses" due to water load are:

$$s_\theta = p\, h\, [-\, 0.4178 - 0.01424 \cos \theta - 1.16 \cos 2\theta - 0.03726 \cos 3\theta$$
$$-\, 0.006177 \sin \theta + 0.2303 \sin 2\theta + 0.006177 \sin 3\theta] \ldots\ldots (35)$$

Stresses Due to Mass.—Let $c_1 = c \cos \beta = 0.7431\, c$; and, $c_2 = c \sin \beta = 0.6691\, c$. From Equations (27): $A_0 = -\, 0.1616\, c\, h$; $A_2 = -\, 0.02780\, c\, h$; and, $B_2 = -\, 0.07180\, c\, h$.

The "hoop stresses" due to mass are combined with System II:

$$s_\theta = c\, h \Big[-0.3232 + 0.02204 \cos \theta + 0.1112 \cos 2\theta - 0.006678 \cos 3\theta + 0.01365 \sin \theta + 0.2872 \sin 2\theta - 0.01365 \sin 3\theta \Big] \dots\dots\dots (36)$$

Combining Equations (35) and (36) the "hoop stresses" due to water and mass are, when $c = 0.27\, p$, as follows:

$$s_\theta = p\, h \Big[-0.5051 - 0.00829 \cos \theta - 1.13 \cos 2\theta - 0.03906 \cos 3\theta - 0.00249 \sin \theta + 0.3078 \sin 2\theta + 0.00249 \sin 3\theta \Big] \dots\dots\dots (37)$$

TABLE 1.—Hoop Stresses Due to Combined Mass and Water Loads ($p\, h = 771$ lb per in.^{2})

− = Compression			+ = Tension		
θ	s_θ	Unit stress, in pounds per square inch	θ	s_θ	Unit stress, in pounds per square inch
0	$-1.6825\, p h$	−1300	180	$-1.5877\, p h$	−1221
30	$-0.8094\, p h$	−623	210	$-0.7976\, p h$	−613
60	$+0.3583\, p h$	+276	240	$+0.2937\, p h$	+226
90	$+0.6200\, p h$	+478	270	$+0.6300\, p h$	+485
120	$-0.2438\, p h$	−188	300	$-0.1696\, p h$	−131
150	$-1.3282\, p h$	−1022	330	$-1.3451\, p h$	−1035

These stresses are plotted in Fig. 4 and the unit stresses are given in Table 1. Maximum tensile stresses exist in the neighborhood of $\theta = 90°$ and $\theta = 270$ degrees. For $\theta = 90°$, the circumferential stress, s_θ, as a function of $\left(\frac{\rho}{r_h}\right)$ is given by;

$$s_\theta = p\, h \Big[-0.2525 \left(1 + \frac{r^2_h}{\rho^2}\right) - 0.000622 \left(3\, \frac{\rho}{h} + \frac{r^3_h}{\rho^3}\right) + 0.2825 \left(3 \frac{r^4_h}{\rho^4} + 1\right) \times 0.000622 \left(-\frac{\rho}{r_h} + \frac{r^3_h}{\rho^3} - 4\, \frac{r^5_h}{\rho^5}\right) \Big] \dots\dots\dots (38)$$

These stresses are plotted in Fig. 5.

To determine the total tension which must be taken by the reinforcing steel the area under the curve of Fig. 5 may be determined, or the following integral evaluated:

$$\text{Total tension} = \int_{r_h}^{2.5 r_h} s_\theta \, d\rho \dots\dots\dots (39)$$

in which s_θ as given by Equation (38) is to be inserted in Equation (39). The upper limit is determined by an examination of Fig. 5. Performing the integration: Total tension $= ph\, r_h\, [-0.2525\ (2.1) - 0.000622\ (8.295) + 0.2825 \times 2.436 + 0.000622\ (-\ 3.1794)] = 68\,988$ lb. Using an average stress of 18 000 lb per sq in., the area of steel required is $\frac{68\,988}{18\,000} = 3.83$ in.^{2} The spacing of this steel is easily determined from a consideration of Fig. 5. The percentage of steel is $\frac{3.83}{(1.5\ r_h)\ (144)} = 0.444$ per cent. These values are for a unit thickness of buttress.

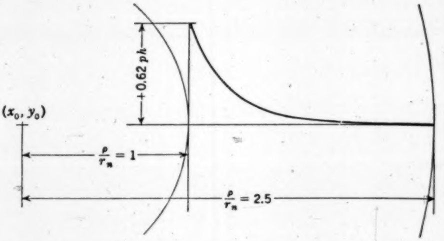

FIG. 5.—VARIATION OF s_θ STRESS ALONG SECTION $\theta = 90$ DEGREES

CONCLUSIONS

The formulas derived in this paper enable the designer to determine the regions around openings in dams and buttresses where tensile stresses may exist. Stress trajectories may also be determined by use of these equations. Furthermore, an estimate may be obtained of the reinforcement needed to take care of such tensile stress. In the case of gravity dams these equations are limited to longitudinal galleries.

APPENDIX I

NOTATION

In the following notation, presented for convenience of reference, an effort has been made to conform as nearly as practicable with "Symbols for Mechanics, Structural Engineering, and "Testing Materials", advanced by the American Standards Association.[2] Symbols used simply as general mathematical coefficients are not included in the list, their definitions being given clearly in the text. Where such coefficients conflict with symbols also used in the paper (such as c = mass), the distinction is explained at each point.

C = a constant;
c = weight per unit volume;
F = the Airy stress function;

f = a substitution factor defined by Equations (47*d*) and (47*h*), Appendix II;

G = a substitution factor defined by Equation (46*b*), Appendix II;

g = the gravity constant; also, where so indicated, g_n = a substitution factor defined by Equations (47*e*) and (47*i*), Appendix II;

h = height; also, where so indicated, h_n = a substitution factor defined by Equations (47*f*) and (47*j*), Appendix II;

J = a substitution factor defined by Equation (47*c*), Appendix II;

K = $\tan \alpha$ = a substitution factor;

k_n = a substitution factor defined by Equations (47*g*) and (47*k*), Appendix II; $k_2 = \cot \alpha$;

$\left.\begin{matrix} M_1 \\ M_2 \\ M_3 \end{matrix}\right\}$ = (see Equations (48), (49), and (50), Appendix II);

n = an abstract number;

p = unit, hydrostatic water pressure;

q = the ratio, $\dfrac{r_i}{r_o}$;

r = radius of a circle, as distinct from the polar co-ordinate distance, ρ; r_h = radius of a circular hole; r_i = the inner radius of an annular ring; r_o = outer radius of an annular ring;

s = unit stress in general; in particular, s = total axial load divided by gross area; s_n = normal stress; s_s = shear stress; s_x = stress in an X-direction; s_y = stress in a Y-direction; s_ρ = stress in a radial plane; s_θ = stress perpendicular to a radial plane at any angle, θ; s_I = stresses defined as belonging to System I; s_{II} = stresses defined as belonging to System II;

x = distance measured in an X-direction; x_0 = the x-co-ordinate of center of hole;

y = distance measured in a Y-direction; y_0 = the y-co-ordinate of center of hole;

α = angle between the battered faces of a dam.

θ = angular distance; a polar co-ordinate;

ρ = a radial distance; polar co-ordinate;

APPENDIX II

ANALYSIS OF ANNULAR RING

An annular ring of outer radius, r_o, inner radius, r_i subjected to the boundary stresses as given by Equations (13) can best be studied by use of Airy's function in polar co-ordinates. Corresponding to Equation (7) in cartesian co-ordinates, there is a similar equation in polar co-ordinates:

$$\left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho}\frac{\partial}{\partial \rho} + \frac{1}{\rho^2}\frac{\partial^2}{\partial \theta^2}\right)\left(\frac{\partial^2 \phi}{\partial \rho^2} + \frac{1}{\rho}\frac{\partial \phi}{\partial \rho} + \frac{1}{\rho^2}\frac{\partial^2 \phi}{\partial \theta^2}\right) = 0 \quad \ldots (40)$$

with stresses defined as follows:

$$\left.\begin{aligned} s_\rho &= \frac{1}{\rho}\frac{\partial\phi}{\partial\rho} + \frac{1}{\rho^2}\frac{\partial^2\phi}{\partial\rho^2} \\ s_\theta &= \frac{\partial^2\phi}{\partial\theta^2} \\ s_s &= -\frac{\partial}{\partial\rho}\left(\frac{1}{\rho}\frac{\partial\phi}{\partial\theta}\right) \end{aligned}\right\} \qquad (41)$$

and,

The general solution[5] of Equation (40) is:

$$\begin{aligned} \phi &= a_0 \log\rho + b_0\rho^2 + c_0\rho^2\log\rho + d_0\rho^2\theta + a'_0\theta \\ &+ \frac{a_1}{2}\rho\,\theta\sin\theta + \left(b_1\rho^3 + a'_1\rho^{-1} + b'_1\rho\log\rho\right)\cos\theta \\ &- \frac{c_1}{2}\rho\,\theta\cos\theta + \left(d_1\rho^3 + c'_1\rho^{-1} + d'_1\rho\log\rho\right)\sin\theta \\ &+ \sum_{n=2}^{n=\infty}\left(a_n\rho^n + b_n\rho^{n+2} + a'_n\rho^{-n} + b'_n\rho^{-n+2}\right)\cos n\theta \\ &+ \sum_{n=2}^{n=\infty}\left(c_n\rho^n + d_n\rho^{n+2} + c'_n\rho^{-n} + d'_n\rho^{-n+2}\right)\sin n\theta \qquad (42) \end{aligned}$$

in which a_n, b_n, c_n, and d_n are mathematical constants. In order that the stress distribution and displacements may be single valued, $c_0 = d_0 = 0$; and in order to satisfy the boundary conditions imposed by Equations (13):

$$a_0 = -\frac{r_o^2\,q^2}{1-q^2}A_0 \qquad (43a)$$

and,

$$b_0 = \frac{1}{2}\frac{A_0}{1-q^2} \qquad (43b)$$

From the fact that $A_1 = D_1$ and $B_1 = -C_1$, it follows that $d'_1 = b'_1 = 0$. In their complete study of the circular ring, Messrs. Coker and Filon[6], have shown that the remaining constants are given by,

$$b_1 r_o = \frac{A_1}{2(1-q^4)} \qquad (44a)$$

$$a_1 = \frac{A_1 r_o^3 q^4}{2(1-q^4)} \qquad (44b)$$

$$d_1 r_o = \frac{B_1}{2(1-q^4)} \qquad (44c)$$

and,

$$c'_1 = \frac{B_1 r^3_o q^4}{2(1 - q^4)} \tag{44d}$$

When n is equal to, or greater than, 2:

$$b_n r_o^n = Q_n f_n - G_n g_n \tag{45a}$$

$$a_n r_o^{n-2} = Q_n g_n - J_n f_n \tag{45b}$$

$$a'_n r_o^{-n} b^{-2} = Q_n h_n - G_n k_n \tag{45c}$$

$$b'_n r_o^{-n} = Q_n k_n - J_n h_n \tag{45d}$$

$$\mathrm{d}_n \mathrm{r}_o^n = Q_n f'_n - G_n g'_n \tag{45e}$$

$$c_n r_o^{n-2} = Q_n g'_n - J_n f'_n \tag{45f}$$

$$c'_n r_o^{-n} b^{-2} = Q_n h'_n - G_n k'_n \tag{45g}$$

and,

$$d'_n r_o^{-n} = Q_n k'_n - J_n h'_n \tag{45h}$$

in which,

$$Q_n = \frac{1 - q^{2n}}{2n\,[(1 - q^{2n})^2 - n^2 q^{2n-2} (1 - q^2)^2]} \tag{46a}$$

$$G_n = \frac{1 - q^{2n-2}}{2(n + 1)\,[(1 - q^{2n})^2 - n^2 q^{2n-2} (1 - q^2)^2]} \tag{46b}$$

$$J_n = \frac{1 - q^{2n+2}}{2(n - 1)\,[(1 - q^{2n})^2 - n^2 q^{2n-2} (1 - q^2)^2]} \tag{46c}$$

$$f_n = n(A_n - D_n) \tag{46d}$$

$$g_n = n A_n - (n + 2) D_n \tag{46e}$$

$$h_n = -q^{2n-2} (n A_n + (n - 2) D_n) \tag{46f}$$

$$k_n = -n q^{2n} (A_n + D_n) \tag{46g}$$

$$f'_n = n(B_n + C_n) \tag{46h}$$

$$g'_n = n B_n + (n + 2) C_n \tag{46i}$$

$$h'_n = -q^{2n-2} \{ n B_n - (n - 2) C_n \} \tag{46j}$$

and,

$$k'_n = -n q^{2n} \{ B_n - C_n \} \tag{46k}$$

Substituting values of A_n in Equations (14) into Equations (46), the factors are determined to be as listed in Table 2. These values can be used

TABLE 2.—LIST OF FACTORS IN EQUATIONS (46), IN TERMS OF A_n AND B_n

Values of n	f	f'	g	g'	h	h'	k	k'
2	$4A_2$	$4B_2$	$6A_2$	$6B_2$	$-2q^2A_2$	$-2q^2B_2$	0	0
3	$6A_3$	$6B_3$	$8A_3$	$8B_3$	$-2q^4A_3$	$-2q^4B_3$	0	0

for the solution of Equations (45). Assuming that a plate is infinite so that $q = \frac{r_1}{r_o} = 0$, the stresses, s_O, s_θ, and s_s, can be obtained by the use of Equations (41) to (45), inclusive, the result being as follows:

$$\begin{aligned} s_\rho = {} & A_o\left(1 - \frac{r^2_h}{\rho^2}\right) + r_h\left(M_1 \cos\theta + M_2 \sin\theta\right)\left(\frac{\rho}{r_h} - \frac{r^3_h}{\rho^3}\right) \\ & - \left(A_2 \cos 2\,\theta + B_2 \sin 2\,\theta\right)\left(4\,\frac{r^2_h}{\rho^2} - 1 - 3\,\frac{r^4_h}{\rho^4}\right) \\ & - r_h\left(M_3 \cos 3\,\theta + M_2 \sin 3\,\theta\right)\left(-\frac{\rho}{r_h} + 5\,\frac{r^3_h}{\rho^3} - 4\,\frac{r^3_h}{\rho^3}\right) \qquad \text{......(47)} \end{aligned}$$

$$\begin{aligned} s_\theta = {} & A_o\left(1 + \frac{r^2_h}{\rho^2}\right) + r_h\left(M_1 \cos\theta + M_2 \sin\theta\right)\left(3\,\frac{\rho}{r_h} + \frac{r^5_h}{\rho^5}\right) \\ & - \left(A_2 \cos 2\,\theta + B_2 \sin 2\,\theta\right)\left(3\,\frac{r^4_h}{\rho^4} + 1\right) \\ & + r_h\left(M_3 \cos 3\,\theta + M_2 \sin 3\,\theta\right)\left(-\frac{\rho}{r_h} + \frac{r^3_h}{\rho^3} - 4\,\frac{r^5_h}{\rho^5}\right) \qquad \text{.......(48)} \end{aligned}$$

and,

$$\begin{aligned} s_s = {} & r_h\left(\frac{\rho}{r_h} - \frac{r^3_h}{\rho^3}\right)\left(M_1 \sin\theta - M_2 \cos\theta\right) \\ & + \left(3\,\frac{r^4_h}{\rho^4} - 1 - 2\,\frac{r^2_h}{\rho^2}\right)\left(A_2 \sin 2\,\theta - B_2 \cos 2\,\theta\right) \\ & + r_h\left(4\,\frac{r^5_h}{\rho^5} - \frac{\rho}{r_h} - 3\,\frac{r^3_h}{\rho^3}\right)\left(M_3 \sin 3\,\theta - M_2 \cos 3\,\theta\right) \qquad \text{.......(49)} \end{aligned}$$

in which $M_1 = -\frac{p}{4\,K^3}\left(K^3 - K\right)$; $M_2 = -\frac{p}{2\,K^3}$; and $M_3 = \frac{p}{4\,K^3}\left(K^3 + 3\,K\right)$

DISCUSSION

R. D. MINDLIN,[7] JUN. AM. SOC. C. E. (by letter).—In examining Equations (28), (29), (30), and (34) for the stresses around a circular hole resulting from the gravitational action of a dam, it is observed that the elastic constants of the material are not involved. This is surprising in the light of a recent extension by M. A. Biot[8] of a theorem by J. H. Michell[9].

Michell's theorem applies to a two-dimensional stress system in a region pierced by holes, no body forces being present. He showed that in such a system the stresses are independent of the elastic constants only if the resultant force over each hole vanishes. This conclusion is found necessary in order to assure single-valuedness of the displacements.

Biot has extended Michell's theorem to the case of gravity stresses. He has shown[8] that "in a solid two-dimensional homogeneous body the stresses due to gravity do not depend on the elasticity constants of the material; they do, however, in general for a body with holes." Therefore, a more detailed examination of the stresses due to mass is indicated.

The author has conveniently divided the stresses in the solid dam into two systems. In System I the stresses on any closed boundary produce zero resultant force. Hence, the additional stresses required to remove the normal and shearing stresses on the periphery of a circular hole also involve zero resultant force on the hole. No difficulty with many valued displacements is encountered, therefore, in dealing with System I, and the author has found the required stress system by a well known method.

In dealing with System II, Mr. Silverman has observed that these stresses produce a resultant force on an internal circular boundary equal to the weight of the enclosed disk. In order to remove the stresses from the periphery of the hole, an additional stress system must be superposed which yields equal and opposite stresses on the circular boundary. The latter system, then, must involve a resultant stress on the hole equal and opposite to the weight of the enclosed disk of radius, r_h. Therefore, according to Michell's theorem, the superimposed system should involve the elastic constants. This was to be expected from Biot's theorem. In fact, the foregoing explanation is simply a derivation of Biot's theorem for the present case.

If the elastic constants do not appear in a case where the resultant force on an internal boundary does not vanish, then, by Michell's theorem, the displacements resulting from the stresses should be many valued. Furthermore, when the internal boundary is closed, as in this case, many-valued functions in the displacements are not permissible, and a solution containing them is not valid.

[9] "On the Direct Determination of Stress in an Elastic Solid, with Application to the Theory of Plates", by J. H. Michell, *Proceedings*, London Math. Soc. Vol. XXXI (1899), p. 100.

It is necessary, therefore, to proceed to examine the stress function (Equation (33)) which was used to annul the stresses on the boundary, $\rho = r_i$. Writing $c\, r^2_i = a_1$, Equation (33) becomes:

$$F_1 = \frac{a_1}{2}\, \rho\, \theta \sin \theta \qquad (50)$$

The stress function given in Equation (50) is known to produce many-valued functions in the displacements of the form[10], $\frac{a_1}{2}\,\frac{(1-\nu)}{E}\,\theta \sin \theta$; and $\frac{a_1}{2}\,\frac{(1-\nu)}{E}\,\theta \cos \theta$, respectively, in which ν = Poisson's ratio. This was to be expected from the preceding analysis, and it may be concluded that the stress system represented by Equations (34) is not possible in a continuous elastic medium.

To obtain the correct system of stress required to remove the stresses on the periphery of the hole, a bi-harmonic stress function must be found which will satisfy the following conditions:

(1) The displacements introduced by the stress function must be single-valued;

(2) The normal and shearing stresses on the circular boundary, $\rho = r_i$, must be equal and opposite to those of System II; and,

(3) All the stresses introduced by the new function must approach zero as ρ approaches infinity.

In order to satisfy Condition (1) one must combine with Equation (50) a stress function[10],

$$F_2 = b'_1\, \rho \log \rho \cos \theta \qquad (51)$$

in which,

$$b'_1 = -\,\frac{a_1\,(1-\nu)}{4} \qquad (52)$$

The combined functions, F_1 and F_2, satisfy Conditions (1) and (3), but not Condition (2). The addition of F_2 to the system has served to introduce shearing stresses on the circular boundary (proportional to $\sin \theta$), which are not present in System II or in F_1. Therefore, another function, F_3, must be added, which will remove these shearing stresses without introducing normal stresses on the circular boundary other than those proportional to $\cos \theta$. Furthermore, F_3 must satisfy Conditions (1) and (3). Such a function is given by:

$$F_3 = a'_1\, \rho^{-1} \cos \theta \qquad (53)$$

The complete stress function is then given by:

$$F = F_1 + F_2 + F_3 = \frac{a_1}{2}\, \rho\, \theta \sin \theta + b'_1\, \rho \log \rho \cos \theta + a'_1\, \rho^{-1} \cos \theta \qquad (54)$$

---

[10] See "Theory of Elasticity", by S. Timoshenko, p. 116, McGraw-Hill, 1934.

To determine the values of the constants it is necessary first to calculate the stresses. Using Equations (20) of the paper, these are found to be:

$$s_\rho = \left(\frac{a_1}{\rho} + \frac{b'_1}{\rho} - \frac{2\,a'_1}{\rho^3} - c\,\rho\right)\cos\theta \;\dots\dots\dots\dots\;(55a)$$

$$s_\theta = \left(\frac{b'_1}{\rho} + \frac{2\,a'_1}{\rho^3} - c\,\rho\right)\cos\theta \;\dots\dots\dots\dots\;(55b)$$

and,

$$s_s = \left(\frac{b'_1}{\rho} - \frac{2\,a'_1}{\rho^3}\right)\sin\theta \;\dots\dots\dots\dots\;(55c)$$

Condition (2) is expressed by the equation:

$$[s_\rho]_{\rho=r_i} = [s_s]_{\rho=r_i} = 0 \;\dots\dots\dots\dots\;(56)$$

and, hence:

$$\frac{a_1}{r_i} + \frac{b'_1}{r_i} - \frac{2\,a'_1}{r^3_i} - c\,r_i = 0 \;\dots\dots\dots\dots\;(57a)$$

and

$$\frac{b'_1}{r_i} - \frac{2\,a'_1}{r^3_i} = 0 \;\dots\dots\dots\dots\;(57b)$$

Condition (1) is expressed by Equation (52). Solving for the three unknowns in Equations (52) and (57):

$$a_1 = c\,r^2_i \;\dots\dots\dots\dots\;(58a)$$

$$b'_1 = -\frac{1-\nu}{4}\,c\,r^2_i \;\dots\dots\dots\dots\;(58b)$$

and,

$$a'_1 = -\frac{1-\nu}{8}\,c\,r^4_i \;\dots\dots\dots\dots\;(58c)$$

Substituting these values in Equation (54) the final stress function becomes:

$$F = \frac{1}{2}\,c\,r^2_i\,\rho\,\theta\sin\theta - \frac{1-\nu}{4}\,c\,r^2_i\,\rho\log\rho\cos\theta - \frac{1-\nu}{8}\,c\,r^4_i\,\rho^{-1}\cos\theta \;\dots\;(59)$$

The corresponding stresses are, from Equations (20):

$$s_\rho = c\left(\frac{3+\nu}{4}\,\frac{r^2_i}{\rho} + \frac{1-\nu}{4}\,\frac{r^4_i}{\rho^3} - \rho\right)\cos\theta \;\dots\dots\dots\;(60a)$$

$$s_\theta = -\,c\left(\frac{1-\nu}{4}\,\frac{r^2_i}{\rho} + \frac{1-\nu}{4}\,\frac{r^4_i}{\rho^3} + \rho\right)\cos\theta \;\dots\dots\dots\;(60b)$$

and,

$$s_s = c\left(-\,\frac{1-\nu}{4}\,\frac{r^2_i}{\rho} + \frac{1-\nu}{8}\,\frac{r^4_i}{\rho^3}\right)\sin\theta \;\dots\dots\dots\;(60c)$$

Equations (60) express the correct stresses for System II. By virtue of Equation (52), Condition (1) is satisfied; by virtue of Equations (57*a*) and (57*b*), Condition (2) is satisfied; and an examination of Equations (60) shows that Condition (3) is satisfied. The hoop stresses at the circular boundary are found by substituting $\rho = r_i$ in Equation (60*b*):

$$[s_\theta]_{\rho=r_i} = -\left(\frac{3-\nu}{2}\right) c\, r_i \cos\theta \quad \text{.................} (61)$$

The foregoing analysis has been made for the case of plane stress. It is approximately applicable to a buttress if the diameter of the hole is small in comparison with its distance from the nearest edge of the buttress, and if the thickness of the buttress is small in comparison with the diameter of the hole. For the case of a longitudinal hole in a gravity section the stresses should be transformed to the corresponding system for plane strain.

Additional references should be given to the results of previous stress analyses for the wedge section. The stress systems represented by Equations (8) to (12) and (22) to (25), inclusive, are due to M. Levy[11] and may be obtained from equations given by Love[12]. This stress system applies only to portions of a dam remote from the base. Hence, in addition to the requirement that the small hole be far from the faces of the dam, it must also be far from the base.

Equations (8) and (22) are seen to be of the same form, differing only in the constants associated with the terms of the third degree polynomial. Equation (22) represents the stress which the author has designated as System I. Hence, the additional stress functions, required to annul the stresses due to System I on a circular boundary, will be the same as the stress functions required to annul the stresses on the circular boundary resulting from the water loading, except for the constants. Therefore, a solution of the problem of the stresses due to mass really includes that of the problem of stresses due to water load.

The author is undoubtedly unaware of a previous solution of this problem by G. Nishimura and T. Takayama[13]. Of the two solutions, the writer prefers that of Mr. Silverman as being far less cumbersome. Very skilfully the author has applied what mathematicians would call an elegant method and, independently, has obtained the solution of an interesting problem.

CHESLEY J. POSEY,[14] JUN. AM. SOC. C. E. (by letter).—The author is to be commended for presenting an analytical proof of the existence of tensile stresses near longitudinal circular holes in concrete gravity dams. The question of the proper reinforcement around holes is of importance in many types of concrete design. Although most designers would provide extra reinforcement around a hole in a girder web, many would not admit that any was necessary for a long, relatively small hole in mass concrete. Mr. Silverman's analysis, made on the basis of reasonable assumptions, shows that such reinforcement is necessary for longitudinal holes in gravity dams, to resist stresses due to water and mass loads. In some cases, stresses around the openings, due to volumetric changes from shrinkage and temperature, may call for even more reinforcement.

The proper placing of steel bars around holes is of great importance. The steel should never follow around the inside of a hole, for if it is stressed in tension it will tend to straighten, causing tension in the concrete. As soon as this concrete fails, the steel is useless, and cracking is perhaps further advanced than if no steel had been used. Fig. 6(*a*) is an example of incorrect, and Figs. 6(*b*), 6(*c*), and 6(*d*) of correct, placing of the reinforcement around holes. The placing shown in Fig. 6(*d*) is preferable to that shown in Fig. 6(*c*), however. Diagonal bars should be provided at the corners of rectangular holes, for cracks tend to form at the corners, where vertical and horizontal bars are relatively less effective than diagonal bars. If it is certain that tensile stresses can never occur across one of the diagonal sections, the bars crossing that section may be omitted.

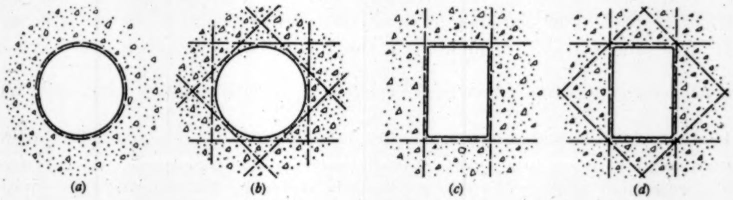

FIG. 6.—METHODS OF PLACING STEEL REINFORCEMENT AROUND HOLES IN MASS CONCRETE

Referring to Fig. 5 of the paper, it is seen that the tensile stresses decrease very rapidly away from the surface of the hole. The steel bars, therefore, should be as close to the surface of the hole as is practicable. The length of bar to be used cannot be computed by any method known at present, and, in the absence of test data, it must be arbitrarily assumed, say, equal to twice the diameter of the hole. The size of bar should then be selected so that the total bond on one-half its length is equal to or greater than its ultimate strength. To prevent cracks, the bar should have as high a ratio of bond stress to slip as is possible. Tests[15] by the writer show that the most favorable ratio is obtained if the bars are straight, and if their surface is rough.

J. H. A. BRAHTZ,[16] ESQ. (by letter).—A new approach is presented in this paper, in the analysis of the stresses in the vicinity of a cylindrical opening in a triangular gravity dam when the axis of the opening is parallel to the face of the dam. The main assumptions are that: (1) The water surface is at the theoretical apex of the dam; (2) the opening is far removed from the faces of the dam; (3) the material is perfectly elastic; and (4) the tensile stresses are so small that the concrete does not crack and, if it does crack, that sufficient steel reinforcement will make the dam act as a homogeneous elastic material.

---

[15] "Tests of Anchorages for Reinforcing Bars", *Bulletin 3*, Univ. of Iowa Eng. Studies.

[16] Director, Photoelastic Laboratory, U. S. Bureau of Reclamation, Denver, Colo.

The method is also applicable to a triangular buttress of a hollow dam if the elastic interaction between the up-stream slab or arches and the buttress is ignored. Even if the results obtained are not exact (and, in one instance, incorrect in principle, as will be shown subsequently), it is believed that stresses computed by the author's method will agree quite closely with those obtained by the approximate methods used by the U. S. Bureau of Reclamation. One of these methods, also based on Assumptions (2) to (4), uses the exact solution by Kirsch for a circular hole in an infinite plate acted upon by uniform boundary forces equal to the principal stresses computed in the structure at the center of the opening as if the opening did not exist.[17] This method is far simpler in application than that developed by Mr. Silverman and is useful not only for the specific type of structure and loading treated by him, but for any type of structure and loading in which the principal stresses can be computed at the center of the opening.

Both methods are approximate and are limited to openings at least three times the radius of the opening from the nearest boundary of the structure. In fact, the author's formulas may be restricted to even greater distances since he assumes that $\frac{r_i}{r_o} = 0$ in arriving at Equations (47), (48), and (49). It is evident that the circle, $\rho = r_o$ must lie within the structure, which implies that the opening must be many times r_i removed from the boundaries. The region of validity should be definitely stated by the author. An approximate theory is of little value in practice without a stipulation of the limits of validity.

If the opening is dangerously close to the boundaries of the structure, or if its shape deviates too much from a circle, it is customary at the Bureau of Reclamation to check the approximate analysis by photo-elastic experimentation.[18]

It has been stated that the author's approach is somewhat more laborious than the methods now in vogue, but even so, it has great merit if it is used only as a check on these other methods. It would certainly be of great interest if Mr. Silverman would compare numerical results obtained by each method under identical conditions. In doing this the tensile stresses and the necessary steel reinforcement should be computed over the maximum line, which, in the author's example, is seen by Fig. 4 to occur at about $\theta = +83°$ and $\theta = -103°$, and not at $\theta = \pm 90$ degrees.

A source of uncertainty in the results obtained by both methods of approach is the change in behavior of the structure caused by the reinforcement steel (if such is needed). This question has been discussed by the writer,[17] including the effect of temperature changes and a uniform pressure acting in the circular opening.

[17] *Technical Memorandum No. 457*, U. S. Bureau of Reclamation.

[18] *Loc. cit., No. 451*, U. S. Bureau of Reclamation.

In publishing solutions of elastic two-dimensional problems many writers consider it necessary to repeat the general theory of the Airy-Maxwell stress function, including the equilibrium equations, stress definitions, and the differential equation which expresses compatibility in accordance with Hooke's generalized stress-strain relations. This seems a needless waste of space, inasmuch as many good references are available. On the other hand, important steps are often omitted which would clarify the situation for the inexperienced reader and facilitate checks on the mathematical procedure.

In the present case the process of transforming the stress functions to the new origin ($x_0\, y_0$) should be given in some detail, because it is of fundamental importance and of general use, and no reference is readily available in case body forces are involved. In manipulating stress functions which represent body forces (weight, inertia, percolation), one soon discovers that it is "tricky" and full of pitfalls.

Change of Co-Ordinates.—The author does not state the definitions of stresses in rectangular components, when body forces, c_1 and c_2, are present. It is here to be noted that more than one stress definition is possible, but if the stress function shall have the same form in rectangular and polar co-ordinates, the writer has shown[19] that the stresses must be defined as follows in rectangular components:

$$s_x = \frac{\partial^2 F}{\partial y^2} - c_1\, x - c_2\, y \quad \text{.................. (62a)}$$

$$s_y = \frac{\partial^2 F}{\partial x^2} - c_1\, x - c_2\, y \quad \text{.................. (62b)}$$

and,

$$s_{xy} = -\frac{\partial^2 F}{\partial x\ \partial y} \quad \text{........................... (62c)}$$

By comparing the author's function, Equation (22), with the function given by the writer[20] for the same case, it may be inferred that the author's stress definitions in rectangular components, are as in Equations (62).

If the origin is now chosen at a point ($x_0\, y_0$) and if the new axes ($\xi\, \eta$) are parallel with the original axes ($x\, y$), then:

$$x = \xi + x_0 \quad \text{........................ (63a)}$$

and

$$y = \eta + y_0 \quad \text{........................ (63b)}$$

Substituting these values in Equations (62), the stress definitions in the new co-ordinate system become:

---

[19] *Bulletin*, Am. Math. Soc., June, 1934, p. 427.

[20] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), Equation (21), p. 1248.

$$s_\xi = \frac{\partial^2 F'_g}{\partial \eta^2} - c_1 (\xi + x_0) - c_2 (\eta + y_0) \ldots\ldots\ldots\ldots (64a)$$

$$s_\eta = \frac{\partial^2 F'_g}{\partial \xi^2} - c_1 (\xi + x_0) - c_2 (\eta + y_0) \ldots\ldots\ldots\ldots (64b)$$

and,

$$s_{\xi\eta} = - \frac{\partial^2 F'_g}{\partial \xi \; \partial \eta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (64c)$$

in which F'_g is obtained simply by substituting Equations (63) into the expression for F_g. In the present case, F_g is given by Equation (22), so that:

$$F'_g = \frac{1}{6} \left[c_1 (\xi + x_0)^3 + (c_1 k + c_2 - 2 c_2 k^2_2 (\eta + y_0)^3 \right]$$
$$+ 3 c_2 k_2 (\xi + x_0) (\eta + y_0)^2 \ldots\ldots\ldots\ldots\ldots\ldots (65)$$

The stresses are now obtained by Equations (64). If, in general, F' is defined as:

$$F' = F_g' - \frac{1}{2} (c_1 x_0 + c_2 y_0) (\xi^2 + \eta^2) \ldots\ldots\ldots\ldots (66)$$

then the stress definitions in the new co-ordinate system may again be expressed in the same general form as Equations (62), namely:

$$s_\xi = \frac{\partial^2 F'}{\partial \eta^2} - c_1 \xi - c_2 \eta \ldots\ldots\ldots\ldots\ldots\ldots (67a)$$

$$s_\eta = \frac{\partial^2 F'}{\partial \xi^2} - c_1 \xi - c_2 \eta \ldots\ldots\ldots\ldots\ldots\ldots (67b)$$

and.

$$s_{\xi\eta} = - \frac{\partial^2 F'}{\partial \xi \; \partial \eta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (67c)$$

in which F' is given by Equation (66). The polar stress components are given by Equations (20). It is important to note that in order to retain the general stress definitions, Equations (62) or Equations (67), it is necessary to subtract the term, 0.5 $(c_1 x_0 + c_2 y_0)$ $(\xi^2 + y^2)$, from the transformed function, F'_g. When no body forces are involved (that is when $c_1 = c_2 = 0$), the transformation is direct.

If the co-ordinate system is to be rotated through the angle, α, about the origin merely replace θ by $\theta + \alpha$ in Equations (20).

Compatibility.—Mr. Silverman makes use of St. Venant's principle when he states that the stresses in the original structure acting on the circle; $\rho = r_0$, are unaffected by the existence of the opening, if r_0 is large compared with r_i.

This principle is somewhat vague, but has been found to hold in many exact solutions and experiments, if applied properly. If r_o falls inside the structure, it is believed that the principle applies in the present case. This then enables the author to ignore compatibility between the regions inside and outside the circle, $\rho = r_o$, so that he only needs to equate the stresses coming from the inside and the outside regions. However, in setting up Stress System II (Equations (34)), in the annular ring, $\rho = r_o \rightarrow r_i$, due to body forces, he makes use of a stress function of the type, $\theta\ \rho \sin \theta$, which gives multi-valued displacements if the origin is entirely surrounded by elastic material. This is not permissible, of course, because it implies that the annular ring has a slit connecting the inside with the outside region. The edges of this slit will be dislocated and must be brought together again by another stress function, giving rise to what is generally known as "dislocation stresses." These are functions of the elastic properties of the material.[21] The complete function which must be used for the author's Stress System II has been presented by the writer.[20]

If no pressure acts on the inside of the hole, this function may be written, in the author's notation:

$$A \left\{ \frac{1}{\rho} + \frac{2\,\rho \log_e \rho}{r_i^2} \right\} \cos(\theta - \beta) + \frac{r_i^2}{2}\, c\, \rho\, \theta \sin(\theta - \beta) \ldots\ldots (68)$$

The stresses are defined by Equations (20). The constant, A, in Equation (68) must be determined so that displacements are single valued; that is, it must be unchanged if θ is replaced by $\theta + 2\,n\,\pi$, in which n is an arbitrary integer. It will be found that,

$$A = -\frac{1}{8}\, r_i^4\, c\, (1 - \mu) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (69)$$

will make the displacements single valued.[22] It is to be noticed that, in Equation (69) in which μ is Poisson's ratio, A is a function of this elastic property, μ.

The Stress System II is now found by applying Definitions (20) to Function (68):

$$s_\rho = -\frac{r_i}{4}\, c\, (1 - \mu) \left(\frac{r_i}{\rho} - \frac{r_i^3}{\rho^3} \right) \cos(\theta - \beta)$$

$$+ \frac{r_i^2}{\rho}\, c \cos(\theta - \beta) - \rho\, c \cos(\theta - \beta) \ldots\ldots\ldots\ldots (70a)$$

$$s_\theta = -\frac{r_i}{4}\, c\, (1 - \mu) \left(\frac{r_i}{\rho} + \frac{r_i^3}{\rho^3} \right) \cos(\theta - \beta) - \rho\, c \cos(\theta - \beta) \ldots (70b)$$

---

[21] *Proceedings*, Math. Soc., London, Vol. 30, 1900, p. 103; and, also, "The Mathematical Theory of Elasticity", by A. E. H. Love, 1927, p. 221.

[22] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1246; also, "Photo-Elasticity", by Coker and Filon, 1931, p. 327.

and,

$$s_{\rho\theta} = -\frac{r_i}{4}\,c\,(1-\mu)\left(\frac{r_i}{\rho} - \frac{r^3_i}{\rho^3}\right)\sin(\theta-\beta) \;\ldots\ldots\ldots\ldots (70c)$$

It will be seen that s_ρ and $s_{\rho\theta}$ vanish over the circle, $\rho = r_i$; and, that s_ρ and s_θ become equal to $-\, r_o\, c \cos(\theta-\beta)$ and $s_{\rho\theta} = 0$ over the circle, $\rho = r_o$, if $\frac{r_i}{r_o}$ approaches zero, thus satisfying the author's conditions.

Attention should be called to the fact that in the writer's use of Function (68) for the determination of stresses in a fillet of a dam, the constant, A, is arbitrary because the origin is not completely surrounded by elastic material in the case of a fillet, that is, is always less than 2π. (In this connection compare the methods of finding displacements given elsewhere by the writer[22].)

The magnitude of Stress System II is usually negligible in the regions of validity of the author's formulas so that it could safely be ignored entirely. The reason for bringing to light the correction in System II is that an important principle is involved in the general application of stress functions giving multiple-valued displacements for the determination of stresses due to temperature variations and body forces in structures having doubly connected regions.[23]

V. L. FEDOROV,[24] ESQ. (by letter).—The study of the stress distribution near the holes in dams and buttresses is interesting because it may help to discover the cause of cracks, that often originate in inspection galleries. The solution offered by Mr. Silverman is correct only in the case of water load; for the case of the action of mass load it should be modified as outlined in this discussion.[25]

When a circular ring is cut from a massif subjected to internal strain due to its own weight, the resultant stress on the outer face of the hole is not zero, but equal to the weight of the ring. In this case the stress distribution depends on the elastic constants of the material, which fact was discovered by Michell.

Referring to Fig. 7, assume a ring in which r_o is so much greater than r_i that $\frac{r_i}{r_o}$ may be assumed equal to zero for many practical purposes. The stresses are then expressed by:

$$s_{\rho o} = c\Big[A_o + (A_1 - 1)\, r_o \cos\theta + B_1\, r_o \sin\theta + A_2 \cos 2\,\theta + B_2 \sin 2\,\theta$$
$$+ A_3\, r_o \cos 3\,\theta + B_3\, r_o \sin 3\,\theta\Big] \;\ldots\ldots\ldots\ldots\ldots (71a)$$

S. S. R., in partial fulfillment of the requirements for the degree of Candidate of Technical Sciences.

and,

$$s_{30} = c\Big[A_1\, r_o \sin\theta - B_1\, r_o \cos\theta - A_2 \sin 2\,\theta + B_2 \cos 2\,\theta$$
$$- A_3\, r_o \sin 3\,\theta + B_3\, r_o \cos 3\,\theta\Big] \quad\ldots\ldots\ldots\ldots\ldots\ldots (71b)$$

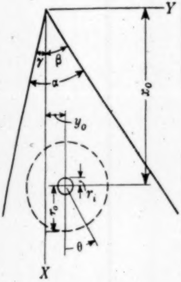

FIG. 7.

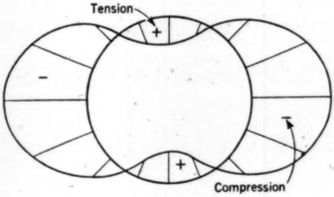

FIG. 8.

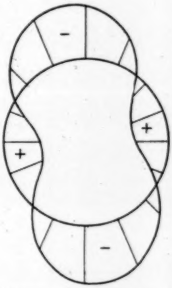

FIG. 9

in which c = weight per unit volume,

$$A_0 = \frac{1}{2}\left[\frac{\sin(\beta-\gamma)\cos\alpha}{\sin^2\alpha}\, y_0 - \left(1 - \frac{2\sin\gamma\sin\beta\cos\alpha}{\sin^2\alpha}\right)x_0\right] \ldots (72a)$$

$$A_1 = \frac{1}{4}\left(1 + \frac{2\sin\gamma\sin\beta\cos\alpha}{\sin^2\alpha}\right) \ldots\ldots\ldots\ldots (72b)$$

$$B_1 = \frac{\sin(\beta-\gamma)\cos\alpha}{4\sin^2\alpha} \ldots\ldots\ldots\ldots\ldots\ldots (72c)$$

$$A_2 = \frac{1}{2}\left[\frac{\sin 2(\beta-\gamma)}{2\sin^2\alpha}\, y_0 - \left(1 - \frac{2\sin\gamma\sin\beta\cos(\beta-\gamma)}{\sin^2\alpha}\right)x_0\right] \ldots (72d)$$

$$B_2 = \frac{\sin\gamma\sin\beta}{\sin^2\alpha}\Big[x_0 \sin(\beta-\gamma) - 2\, y_0 \cos\gamma\cos\beta\Big] \ldots\ldots (72e)$$

$$A_3 = \frac{1}{4}\left[\frac{2\sin\gamma\sin\beta}{\sin^2\alpha}(\sin\gamma\sin\beta + 3\cos\gamma\cos\beta) - 1\right] \ldots (72f)$$

and,

$$B_3 = \frac{\sin(\beta-\gamma)}{4\sin^2\alpha}(\cos\gamma\cos\beta + 3\sin\gamma\sin\beta) \ldots\ldots\ldots (72g)$$

Thus, the stresses in the ring, subjected to load, as determined by Equations (71), are distributed along the outer face (r_o in Fig. 7); there is no load along the inner face, r_i. The stress distribution in this ring may be solved by means of the stress function:

$$\begin{aligned}\phi = c\Big[\, & a_0 \log \rho + l_0 \rho^2 \\ & + \frac{a_1}{2} \rho\, \theta \sin \theta + (l_1 \rho^3 + a'_1 \rho^{-1} + l'_1 \rho \log \rho) \cos \theta \\ & - \frac{c_1}{2} \rho\, \theta \cos \theta + (d_1 \rho^3 + c'_1 \rho^{-1} + d'_1 \rho \log \rho) \sin \theta \\ & + (a_2 \rho^2 + l_2 \rho^4 + a'_2 \rho^{-2} + l'_2) \cos 2\,\theta \\ & + (c_2 \rho^2 + d_2 \rho^4 + c'_2 \rho^{-2} + d'_2) \sin 2\,\theta \\ & + (a_3 \rho^3 + l_3 \rho^5 + a'_3 \rho^{-3} + l'_3 \rho^{-1}) \cos 3\,\theta \\ & + (c_3 \rho^3 + d_3 \rho^5 + c'_3 \rho^{-3} + d'_3 \rho^{-1}) \sin 3\,\theta \Big] \quad \ldots\ldots\ldots\ldots\ldots (73)\end{aligned}$$

The stresses are:

$$\begin{aligned} s_\rho = \frac{1}{\rho}\frac{\partial \phi}{\partial \rho} + \frac{1}{\rho^2}\frac{\partial^2 \phi}{\partial \theta^2} - c\,\rho \cos\theta = c\Big[& \frac{a_0}{\rho^2} + 2\, l_0 \\ & + \left(\frac{a_1 + l'_1}{\rho} + 2\, l_1 \rho - \frac{2\, a'_1}{\rho^3} - \rho\right)\cos\theta + \left(\frac{c_1 + d'_1}{\rho} + 2\, d_1 \rho - \frac{2\, c'_1}{\rho^3}\right)\sin\theta \\ & - \left(2\, a_2 + \frac{6\, a'_2}{\rho^4} + \frac{4\, l'_2}{\rho^2}\right)\cos 2\,\theta - \left(2\, c_2 + \frac{6\, c'_2}{\rho^4} + \frac{4 d'_2}{\rho^2}\right)\sin 2\,\theta \\ & - \left(6\, a_3 \rho + 4\, l_3 \rho^3 + \frac{12\, a'_3}{\rho^5} + \frac{10\, l'_3}{\rho^3}\right)\cos 3\,\theta \\ & - \left(6\, c_3 \rho + 4\, d_3 \rho^3 + \frac{12\, c'_3}{\rho^5} + \frac{10\, d'_3}{\rho^3}\right)\sin 3\,\theta \Big] \quad \ldots\ldots\ldots (74a)\end{aligned}$$

$$\begin{aligned} s_\vartheta = -\frac{\partial}{\partial\rho}\left(\frac{1}{\rho}\frac{\partial \phi}{\partial \theta}\right) = c\Big[& \left(\frac{l'_1}{\rho} + 2\, l_1 \rho - \frac{2\, a'_1}{\rho^3}\right)\sin\theta - \left(2\, d_1 \rho - \frac{2\, c'_1}{\rho^3} + \frac{d'_1}{\rho}\right)\cos\theta \\ & + \left(2\, a_2 + 6\, l_2 \rho^2 - \frac{6\, a'_2}{\rho^4} - \frac{2\, l'_2}{\rho^2}\right)\sin 2\,\theta - \left(2\, c_2 + 6\, d_2 \rho^2 - \frac{6\, c'_2}{\rho^4} - \frac{2\, d'_2}{\rho^2}\right)\cos 2\,\theta \\ & + \left(6\, a_3 \rho + 12\, l_3 \rho^3 - \frac{12\, a'_3}{\rho^5} - \frac{6\, l'_3}{\rho^3}\right)\sin 3\,\theta \\ & - \left(6\, c_3 \rho + 12\, d_3 \rho^3 - \frac{12\, c'_3}{\rho^5} - \frac{6\, d'_3}{\rho^3}\right)\cos 3\,\theta \Big] \quad \ldots\ldots (74b)\end{aligned}$$

and,

$$s_\theta = \frac{\partial^2 \phi}{\partial \rho^2} - c\,\rho \cos\theta = c\left[-\frac{a_0}{\rho^2} + 2\,l_o \right.$$

$$+ \left(6\,l_1\,\rho + \frac{2\,a'_1}{\rho^3} + \frac{l'_1}{\rho} - \rho\right)\cos\theta + \left(6\,d_1\,\rho + \frac{2\,c'_1}{\rho^3} + \frac{d'_1}{\rho}\right)\sin\theta$$

$$+ \left(2\,a_2 + 12\,l_2\,\rho^2 + \frac{6\,a'_2}{\rho^4}\right)\cos 2\,\theta + \left(2\,c_2 + 12\,d_2\,\rho^2 + \frac{6\,c'_2}{\rho^4}\right)\sin 2\,\theta$$

$$+ \left(6\,a_3\,\rho + 20\,l_3\,\rho^3 + \frac{12\,a'_3}{\rho^5} + \frac{2\,l'_3}{\rho^3}\right)\cos 3\,\theta + \left(6\,c_3\,\rho + 20\,d_3\,\rho^3\right.$$

$$\left.\left. + \frac{12\,c'_3}{\rho^5} + \frac{2\,d'_3}{\rho^3}\right)\sin 3\,\theta \right] \ldots\ldots\ldots\ldots\ldots\ldots (74c)$$

The constant coefficients must be found from the boundary conditions: $\rho = r_i$; $s_\rho = 0$; and, $s_\theta = 0$. For $r = r_o$, when $\frac{r_i}{r_o} = 0$, Equations (74) become the same as Equations (71).

For terms containing $\sin 2\,\theta$, $\cos 2\,\theta$, $\sin 3\,\theta$, and $\cos 3\,\theta$, and for terms independent of θ, all coefficients may be found from the foregoing conditions, as follows: $a_0 = -A_o\,r^2_i$; $l_o = \frac{A_o}{2}$; $a_2 = -\frac{A_2}{2}$; $l_2 = 0$; $a'_2 = -\frac{A_2\,r^4_i}{2}$; $l'_2 = A_2\,r^2_i$; $c_2 = -\frac{B_2}{2}$; $d_2 = 0$; $c'_2 = -\frac{B_2}{2}\,r^4_i$; $d'_2 = B_2\,r^2_i$; $a_3 = -\frac{A_3}{6}$; $l_3 = 0$; $a'_3 = -\frac{A_3\,r^6_i}{3}$; $l'_3 = \frac{A_3\,r^4_i}{2}$; $c_3 = -\frac{B_3}{6}$; $d_3 = 0$; $c'_3 = -\frac{B_3}{3}\,r^6_i$; and, $d'_3 = \frac{B_3\,r^4_i}{2}$.

For terms containing $\cos\theta$ and $\sin\theta$:

$$\frac{a_1 + l'_1}{r_i} + 2\,l_1\,r_i - \frac{2\,a'_1}{r^3_i} - r_i = 0 \ldots\ldots\ldots\ldots\ldots (75a)$$

$$\frac{l'_1}{r_i} + 2\,l_1\,r_i - \frac{2\,a'_1}{r^3_i} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (75b)$$

$$\frac{a_1 + l'_1}{r_o} + 2\,l_1\,r_o - \frac{2\,a'_1}{r^3_o} - r_o = (A_1 - 1)\,r_o \ldots\ldots\ldots (75c)$$

$$\frac{l'_1}{r_o} + 2\,l_1\,r_o - \frac{2\,a'_1}{r^3_o} = A_1\,r_o \ldots\ldots\ldots\ldots\ldots (75d)$$

$$\frac{c_1 + d'_1}{r_i} + 2\,d_1\,r_i - \frac{2\,c'_1}{r^3_i} = 0 \ldots\ldots\ldots\ldots\ldots (75e)$$

$$\frac{d'_1}{r_i} + 2\,d_1\,r_i - \frac{2\,c'_1}{r^3_1} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (75f)$$

$$\frac{c_1 + d'_1}{r_o} + 2\,d_1\,r_o - \frac{2\,c_1'}{r^3_o} = B_1\,r_o \ldots\ldots\ldots\ldots\ldots (75g)$$

and,

$$\frac{d'_1}{r_o} + 2\, d_1\, r_o - \frac{2\, c'_1}{r^3_o} = B_1\, r_o \quad \ldots\ldots\ldots\ldots\ldots\ldots (75h)$$

From Equations (75), it is possible to solve for $a_1 = r^2_i$ and $c_1 = 0$, leaving four equations (Equations (75*b*), (75*d*), (75*f*), and 75*h*)), with six unknowns for the solution of the remaining factors. In order that the displacements in the ring shall be single-valued in the case of plane strain, it is necessary to assume[26] that,

$$l'_1 = -\frac{1 - 2\,\mu}{4\,(1 - \mu)}\, a_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (76a)$$

and,

$$d'_1 = -\frac{1 - 2\,\mu}{4\,(1 - \mu)}\, c_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (76b)$$

in which μ is Poisson's ratio for the material. Then: $l'_1 = -\dfrac{1 - 2\,\mu}{4\,(1 - \mu)}\, r^2_i$; $a'_1 = \dfrac{1}{2}\left[A_1 - \dfrac{1 - 2\,\mu}{4\,(1 - \mu)}\right] r^4_i$; $l_1 = \dfrac{A_1}{2}$; $d'_1 = 0$; $c'_1 = \dfrac{B_1}{2}\, r^4_i$; and $d_1 = \dfrac{B_1}{2}$.

Finally, the stresses are:

$$\begin{aligned} s_\rho = c \Bigg\{ & A_0 \left(1 - \frac{r^2_i}{\rho^2}\right) + (A_1 \cos\theta + B_1 \sin\theta) \left(\rho - \frac{r^4_i}{\rho^3}\right) \\ & + \left[\frac{1 - 2\,\mu}{4\,(1 - \mu)} \left(\frac{r^4_i}{\rho^3} - \frac{r^2_i}{\rho}\right) + \frac{r^2_i}{\rho} - \rho\right] \cos\theta \\ & + (A_2 \cos 2\,\theta + B_2 \sin 2\,\theta) \left(1 + \frac{3\, r^4_i}{\rho^4} - \frac{4\, r^2_i}{\rho^2}\right) \\ & + (A_3 \cos 3\,\theta + B_3 \sin 3\,\theta) \left(\rho + \frac{4\, r^6_i}{\rho^5} - \frac{5\, r^4_i}{\rho^3}\right) \Bigg\} \quad \ldots\ldots (77a) \end{aligned}$$

$$\begin{aligned} s_s = c \Bigg\{ & (A_1 \sin\theta - B_1 \cos\theta) \left(\rho - \frac{r^4_i}{\rho^3}\right) + \frac{1 - 2\,\mu}{4\,(1 - \mu)} \left(\frac{r^4_i}{\rho^3} - \frac{r^2_i}{\rho}\right) \sin\theta \\ & - (A_2 \sin 2\,\theta - B_2 \cos 2\,\theta) \left(1 - \frac{3\, r^4_i}{\rho^4} + \frac{2\, r^2_i}{\rho^2}\right) \\ & - (A_3 \sin 3\,\theta - B_3 \cos 3\,\theta) \left(\rho - \frac{4\, r^6_i}{\rho^5} + \frac{3\, r^4_i}{\rho^3}\right) \Bigg\} \quad \ldots\ldots (77b) \end{aligned}$$

\end{aligned}
$$

The foregoing solution may be applied to gravity dams. In the case of hollow dams, the buttresses are considered as thin plates, instead of $\dfrac{1 - 2\,\mu}{4\,(1 - \mu)}$ (see Equation (76*a*), one must substitute $\dfrac{1 - \mu}{4}$.

To demonstrate the characteristics of the results, the hoop stresses around a hole due to mass load in a gravity dam are represented in Fig. 8. There is tension along the upper and lower regions, and compression along the sides. The water load for this dam yields the hoop stress distribution shown in Fig. 9.

F. W. Hanna,[27] M. Am. Soc. C. E. (by letter).—A subject that is very important in the design of dams, is described in this paper. That both longitudinal and transverse cracks appear in the inspection and drainage galleries of most dams is to be expected; and, owing to paucity of data on the subject, the designers of dams are in need of technical information on their cause and prevention. Such technical data are provided, in a large measure, by the author. He is to be congratulated therefore, not only on having introduced the subject, but on having presented a careful and laborious analysis of the particular phase of it involved in buttress dams.

The solutions presented are long and the resulting formulas involved and cumbersome. Some of these troubles could have been avoided by taking the origin of co-ordinates at the center of the circular opening initially and using the computed pressures at this point as constant for limited areas around it, the computed pressures being predicated on the absence of the hole in the buttress. This would have involved some approximation, but not sufficient, in a high dam with the opening near the base, to vitiate the results.

Approximate Formulas for Circular Holes.—The writer suggests the use of an approximate solution of the problem of stresses caused by holes in a dam. Let Fig 10(*a*) represent a section of the theoretical profile of a gravity dam with a circular hole through it near the base to serve as a drainage and inspection gallery. Let p be the computed vertical mass pressure per square foot at the center of the hole calculated on the basis of a solid dam. Consider the section, *aa′ b′b*, as a plate, 1 ft thick, perpendicular to the paper, acted on by a uniform unit vertical pressure of p in the vicinity of the hole as indicated in Fig. 10(*b*). The vertical pressure, p, will be a maximum for reservoir empty, as shown by a comparison of Fig. 10(*b*), with Fig. 10(*c*) showing the vertical pressure, p, for reservoir full.

---

[27] **Cons. Engr., Ankeny, Iowa.**

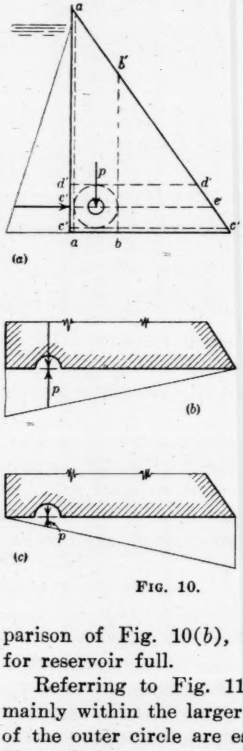

FIG. 10.

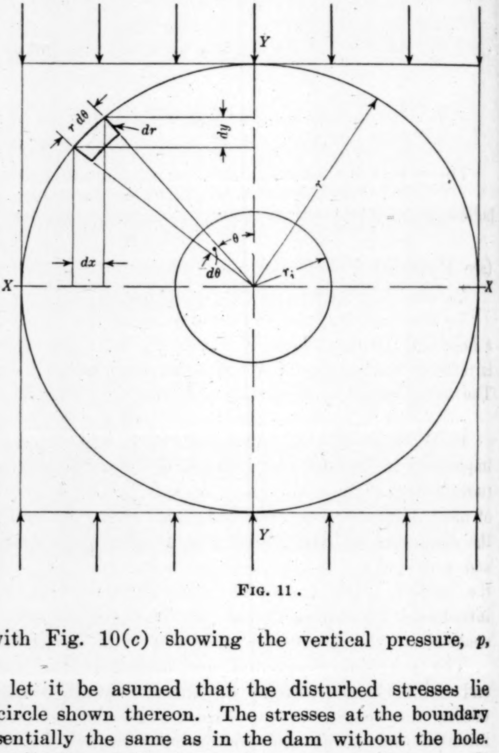

FIG. 11 .

Referring to Fig. 11, let it be asumed that the disturbed stresses lie mainly within the larger circle shown thereon. The stresses at the boundary of the outer circle are essentially the same as in the dam without the hole. The radial stress, s_r, perpendicular to the elementary volume will be $s_r\, r\, d\theta$ and will be balanced by the vertical force, $p\, dx$, resolved on to the opposite side of this volume; therefore, $s_r\, r\, d\theta = p\, dx \cos\theta$, whence $s_r = p \cos\theta\, dx \div r\, d\theta$; therefore,

$$s_r = p \cos^2\theta = \frac{p}{2} + \frac{p}{2}\cos 2\,\theta \qquad (78)$$

In like manner the shearing stress, s_s, would be opposed by the force,

$$s_s = -\,0.5\, p \sin 2\,\theta \qquad (79)$$

and the tangential stress is,

$$s_\theta = p \sin^2 \theta = \frac{p}{2} - \frac{p}{2} \cos 2\,\theta \quad \ldots\ldots\ldots\ldots\ldots\ldots (80)$$

The stress distribution may now be considered as consisting of two parts, one the constant components, $0.5\,p$, and the other the components, $0.5\,p \cos 2\,\theta$, and the shearing force, $0.5\,p \sin 2\,\theta$, both containing functions of θ. The stresses due to these two groups of forces can best be determined separately and their sum taken for their total effect.

The first group of forces act symmetrically around the center of the hole in the dam and is represented by the stress distribution in a thick hollow cylinder subjected to external normal pressure. By adding Equation (78) and Equation (80),

$$s'_r + s'_\theta = p \text{ (a constant)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (81)$$

Now, from Fig. 11, $(s'_r + ds'_r)\,(r + dr) - s'_r = s'_\theta\,dr$, by equilibrating the acting pressure and the resisting stress. Dropping differentials of higher orders,

$$r\,ds'_r + s'_r\,dr = s'_\theta\,dr \quad \ldots\ldots\ldots\ldots\ldots\ldots (82)$$

Solving for s_θ in Equation (81), and substituting the resulting value in Equation (82),

$$r\,ds'_r + s'_r\,dr = (p - s'_r)\,dr \quad \ldots\ldots\ldots\ldots\ldots\ldots (83)$$

Re-arranging,

$$\frac{r\,ds'_r}{s'_r - \frac{p}{2}} = -\frac{2\ dr}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

Integrating,

$$\log\left(s'_r - \frac{p}{2}\right) = \log \frac{C}{r^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (85)$$

Finding the anti-logs of both sides of Equation (85),

$$s'_r - \frac{p}{2} = \frac{C}{r^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (86)$$

When $r = r_1$ in Equation (86), $s'_r = 0$ and, therefore,

$$-\frac{p}{2} = \frac{C}{r^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (87)$$

Solving for C in Equation (87),

$$C = -\frac{p\,r^2_1}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (88)$$

Substituting the value of C just found,

$$s'_r - \frac{p}{2} = - \frac{p\, r_1^2}{2\, r^2} \tag{89}$$

Solving for s'_r in Equation (89), the following important equation is derived,

$$s'_r = \frac{p}{2}\left(1 - \frac{r_1^2}{r^2}\right) \tag{90}$$

Eliminating s'_r between Equation (89) and Equation (81) and solving for s'_θ, the companion important equation is found,

$$s'_\theta = \frac{p}{2}\left(1 + \frac{r_1^2}{r^2}\right) \tag{91}$$

Since functions of θ are not involved in this group of forces, a third important result is obtained,

$$s'_s = 0 \tag{92}$$

Addressing the computations to the solution for the stresses produced by the second group of forces, involving functions of θ, let the Airy stress function, F, be taken as,

$$F = f\,(r) \cos 2\,\theta \tag{93}$$

since F is a function of r and θ. Differentiating Equation (93) twice with respect to θ and noting that the result must hold for $\theta = 0$ as well as for all other values around the center of the hole, there results the equation,

$$\frac{d^2 F}{r^2\, d\,\theta^2} = - \frac{4\, f\,(r)}{r^2} \tag{94}$$

Substituting this value in Equation (21), of the paper, the ordinary differential equation becomes,

$$\left(\frac{d^2}{dr^2} + \frac{d}{r\, dr} - \frac{4}{r^2}\right)\left(\frac{d^2 f}{dr^2} + \frac{df}{r\ dr} - \frac{4\, f}{r^2}\right) = 0 \tag{95}$$

The general solution of this equation, as can be determined by checking back on Equation (94), is,

$$f\,(r) = C_1\, r^2 + C_2\, r^4 + \frac{C_3}{r^2} + C_4 \tag{96}$$

Substituting the value of $f\ (r)$ in Equation (93) there results the following stress function equation,

$$F = \left(C_1\, r^2 + C_2\, r^4 + \frac{C_3}{r^2} + C_4\right) \cos 2\,\theta \tag{97}$$

The last term in each of the author's Equations (20) may be dropped due to assumed constancy of weight in the vicinity of the hole. Then these equations become, respectively,

$$s''_r = \frac{d^2 F}{r^2\, d\,\theta^2} + \frac{dF}{r\, dr} \tag{98a}$$

$$s''_\theta = \frac{d^2\, F}{dr^2} \tag{98b}$$

and,

$$s''_s = \frac{d}{dr}\left(\frac{dF}{r\, d\,\theta}\right) \tag{98c}$$

These are the stress components to be found from the use of Equation (97) and the boundary conditions of the problem. Performing the differentiations on Equation (97) as required by Equations (98) and substituting the results in these equations:

$$s''_r = -\left(2\, C_1 + \frac{6\, C_3}{r^4} + \frac{4\, C_4}{r^2}\right) \cos 2\,\theta \tag{99a}$$

$$s''_\theta = \left(2\, C_1 + 12\, C_2\, r^2 + \frac{6\, C_3}{r^4}\right) \cos 2\,\theta \tag{99b}$$

and,

$$s''_s = \left(2\, C_1 + 6\, C_2\, r^2 - \frac{6\, C_3}{r^4} - \frac{2\, C_4}{r^2}\right) \sin 2\,\theta \tag{99c}$$

The constants are to be determined from the external boundary conditions at a distance as required by Equations (78), (79), and (80), from the fact that the stresses are zero at the edge of the hole, and from the fact that $\frac{r_1}{r} = 0$, approximately, for distant points. Applying these principles and solving the constants it will be found that: $C_1 = -\frac{p}{4}$; $C_2 = 0$; $C_3 = -\frac{p\, r_1^4}{4}$; and $C_4 = \frac{p\, r_1^2}{2}$. Substituting these values in Equations (90):

$$s''_r = \frac{p}{2}\left(1 + \frac{3\, r_1^4}{r^4} - \frac{4\, r_1^2}{r^2}\right) \cos 2\,\theta \tag{100a}$$

$$s''_\theta = -\frac{p}{2}\left(1 + \frac{3\, r_1^4}{r^4}\right) \cos 2\,\theta \tag{100b}$$

and,

$$s''_s = -\frac{p}{2}\left(1 - \frac{3\, r_1^4}{r^4} + \frac{2\, r_1^2}{r^2}\right) \sin 2\,\theta \tag{100c}$$

Now, adding Equations (100) to Equations (90), (91), and (92), respectively, and noting that $s'_r + s''_r = s_r$, $s'_\theta + s''_\theta = s_\theta$, and, $s'_s + s''_s = s_s$, the following final important equations are obtained,

$$s_r = \frac{p}{2}\left[1 - \frac{r^2_1}{r^2} + \left(1 - \frac{4\ r^2_1}{r^2} + \frac{3\ r^4_1}{r^4}\right)\cos 2\,\theta\right] \dots\dots \quad (101a)$$

$$s_\theta = \frac{p}{2}\left[1 + \frac{r^2_1}{r^2} - \left(1 + \frac{3\ r^4_1}{r^4}\right)\cos 2\,\theta\right] \dots\dots\dots (101b)$$

and,

$$s_s = -\frac{p}{2}\left(1 + \frac{2\ r^2_1}{r^2} - \frac{3\ r^4_1}{r^4}\right)\sin 2\,\theta \dots\dots\dots\dots (101c)$$

Equations (101) give, respectively, the radial compression, the tangential tension, and the radial shear in the vicinity of the hole. If the value of r is very large, s_r, s_s, and s_θ approach the values given in Equations (78), (79), and (80). If $r = r_i$, $s_r = s_s = 0$, and $s_\theta = p - 2\,p \cos 2\,\theta$. For $\theta = 90°$ and $270°$, $s_\theta = 3\,p$, the maximum compression at the ends of the horizontal diameter. For $\theta = 0°$ and $180°$, $s_\theta = -\,p$, the maximum tension at the end of the vertical diameter. In general, the compressive stresses are not serious in a dam although they may be quite large, but the tensional stresses at the top and bottom of the hole should be provided for with appropriate steel reinforcement.

Formulas similar to Equations (101) have been developed by several investigators[28] for tension in thin plates. In this discussion they have been developed for compression in thin plates in order to make them apply to dams. Such an application has been made previously.[29]

Approximate Formulas for Elliptical Holes.—Drainage and inspection galleries are not often circular in shape, but generally may be made to approach ellipses. By making the same assumptions as to pressures and as to the use of vertical and horizontal strips of the dam as plates, stress formulas may be developed for elliptical holes.

The development of formulas for the determination of stresses caused by elliptical holes in dams involves the use of curvilinear co-ordinates and hyperbolic functions. Formulas have been developed by Inglis for elliptical plates[30] and they may be applied to holes in dams by making the same assumptions as previously made herein for circular holes. The resultant Inglis formulas applicable to the case are not included herein as the reader can find their development in available engineering literature.

Square Holes.—In dams square holes should be avoided, especially with sharp corners. Rounding the corners with liberal radius helps the stress conditions. The injunction against the use of square holes applies to the customary flat bottoms in otherwise well designed drainage and inspection galleries.

[30] "Stresses in a Plate Due to the Presence of Cracks and Sharp Corners", by C. E. Inglis, *Transactions*, Inst. of Naval Archts., 1913, Pt. I, pp. 219–230.

Limitation of Approximate Formulas.—It is appreciated that the foregoing approximate formulas are not applicable where there is too much variation in the pressure in the vicinity of the hole in the dam, which is the case in a low dam. However, inspection and drainage galleries are not often needed in such structures. In high dams where such openings are needed, the pressures are fairly uniform and only slight error is involved in the assumption that uniformity of pressure exists in the vicinity of the hole both for mass and water pressure. It should be observed that mass pressure is predominant and is at a maximum with the absence of water pressure. When the reservoir is full, nearly all the mass pressure disappears and the horizontal water pressure predominates.

Little valid objection can be made to the assumption that a narrow vertical slice of a gravity dam can be considered as a plate. Gravity dam sections are designed on the basis of the existence of such solitary plates, and this in spite of the effects of Poisson's ratio on their sides. Corrections can be made for the effects of this ratio on the sides of the slice by making a separate computation for a stress equal to 25% of the major force. The effect of Poisson's ratio is to lessen that of the major force.

Cracks in Holes in Dams.—As far as the writer is aware, the Pardee Dam was the first in which reinforcement steel was placed around the drainage and inspection gallery to provide against tension. This gallery is 5 ft wide and 10 ft high, circular at the top and flat at the bottom. The floor of the main gallery is 300 ft below the top of the dam, the average mass pressure, p, being equal to 43 200 lb per sq ft at the center of the gallery.

The equation for the total horizontal tensile force at the top of the gallery, on the assumption that it is circular, is given by[31]:

$$F = -\frac{p r_1}{3\sqrt{3}} \qquad \text{(102)}$$

From Equation (102), based on a radius of 2½ ft, the total horizontal tensile stress at the top of gallery of the Pardee Dam is 20 800 lb. The reinforcement consists of 1-in. square bars placed 1 ft apart, extending entirely around the opening. Nevertheless, there is a hair-crack along the top of the gallery for the entire length. No visible cracks exist at the corners of the flat floor, where they might be expected to be found.

The vertical compressive stress at the ends of the horizontal diameter, as given by Equation (101*b*), is $3\,p = 3 \times 43\,200 = 129\,600$ lb per sq ft, or about 900 lb per sq in., which is not excessive.

If the gallery in the Pardee Dam is assumed to be elliptical with the major axis vertical, and equal to twice the minor axis, the opening in the dam will be more closely approximated. The unit tangential compressive stress at the ends of the horizontal diameter due to mass load is given by the formula,

---

[31] "The Design of Dams", by Hanna and Kennedy, p. 163.

$$s_\theta = p\left(1 + \frac{2\,b}{a}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (103a)$$

and the unit tensile stress at the ends of the vertical diameter is given by the formula.

$$s_\theta = -\,p \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (103b)$$

C. P. Vetter,[32] M. Am. Soc. C. E. (by letter).—The analysis of stresses around a circular gallery in a dam, presented in this paper, follows a method of approach somewhat different from that of previous investigations of the same subject. Such further investigations are of considerable interest since they tend to clarify the problem in the minds of students and designers. The main value, however, lies in comparing results with that of previous work, in emphasizing differences and similarities, in indicating improvement, if any, and in comparing the differences in numerical values obtained by the different methods Any such comparison necessitates giving references to previous work, and such references are often the most valuable part of investigations of this nature. The author has given few such references and has made no such comparisons. The subject has been dealt with in detail by Mr. J. H. A. Brahtz,[33] and it is, therefore, worth investigating to what extent Mr. Silverman has added to present knowledge of the subject.

The paper (see Fig. 1) traces the stresses in a section through a circular hole in a bar subject to uniform tension and refers to the work of Professor S. Timoshenko.[4] In the same book Professor Timoshenko gives[34] the complete solution for stresses at any point of the bar outside the circular opening as well as the proper reference to this well-known Kirsch solution.[35] In the author's notation:

$$s_\rho = \frac{s_x}{2}\left(1 - \frac{r^2_h}{\rho^2}\right) + \frac{s_x}{2}\left(1 + \frac{3\,r^4_h}{\rho^4} - \frac{4\,r^2_h}{\rho^2}\right)\cos 2\,\theta \ \ldots . (104a)$$

$$s_\theta = \frac{s_x}{2}\left(1 + \frac{r^2_h}{\rho^2}\right) - \frac{s_x}{2}\left(1 + \frac{3\,r^4_h}{\rho^4}\right)\cos 2\,\theta \ \ldots\ldots (104b)$$

and,

$$s_s = -\,\frac{s_x}{2}\left(1 - \frac{3\,r^4_h}{\rho^4} + \frac{2\,r^2_h}{\rho^2}\right)\sin 2\,\theta \ \ldots\ldots\ldots (104c)$$

[34] "Theory of Elasticity," by S. Timoshenko, p. 77.

[35] *Zeitschrift*, V. D. I., Vol. 42, 1898.

The tension, s_x, in the bar is herein assumed as acting along the X-axis and θ is assumed as positive in the usual way from the X-axis toward the Y-axis. If, in addition, the bar is subjected to a tension, s_y, along the Y-axis, the total stress in any point may be obtained by substituting $\theta + \frac{\pi}{2}$ for θ in Equations (104) and adding; thus:

$$s_\rho = \frac{s_x + s_y}{2}\left(1 - \frac{r^2_h}{\rho^2}\right) + \frac{s_x - s_y}{2}\left(1 + \frac{3\ r^4_h}{\rho^4} - \frac{4\ r^2_h}{\rho^2}\right) \cos 2\ \theta \quad ..(105a)$$

$$s_\theta = \frac{s_x + s_y}{2}\left(1 + \frac{r^2_h}{\rho^2}\right) - \frac{s_x - s_y}{2}\left(1 + \frac{3\ r^4_h}{\rho^4}\right) \cos 2\ \theta \quad ....(105b)$$

and,

$$s_s = - \frac{s_x - s_y}{2}\left(1 - \frac{3\ r^4_h}{\rho^4} + \frac{2\ r^2_h}{\rho^2}\right) \sin 2\ \theta \quad ....\ (105c)$$

This solution has previously been given by Mr. Brahtz.

If the co-ordinate axes are chosen along the lines of principal stresses, s_1 and s_2, at the location of the center of the hole, Equations (105) will give the stresses at any point around the hole. Along the periphery ($\rho = r_h$), for example:

$$s_\rho = 0 \quad ....(106a)$$

$$s_\theta = s_1 + s_2 - 2\ (s_1 - s_2) \cos 2\ \theta_1 \quad ....(106b)$$

and,

$$s_s = 0 \quad ....(106c)$$

in which θ_1 now is measured from s_1. The symbols, s_1 and s_2, denote the principal stresses in a solid dam at a point corresponding to the center of the hole in the structure under consideration. The assumptions on which Equations (105) and (106) are based are obviously that the hole is very small, as compared with the other dimensions, and is sufficiently far removed from the boundaries of the dam.

The author seems to have avoided the necessity for the former assumption and his Equations (42) to (46), inclusive, apparently only assume that the hole is far away from the boundaries of the dam, but not necessarily that it is very small. However, in order to bring his equations to a form which may be of practical use, the author assumes (see following Table 2) that $q = \frac{r_1}{r_0} = 0$. It should be noted that in the main body of his paper, Mr. Silverman does not state that this assumption lies at the foundation of Equations (15) to (17), inclusive. The assumption that $\frac{r_1}{r_0} = 0$ obviously puts the author's equations on par with Equations (105) and (106), obtained from Kirsch's solution, in that they are all based on the same assumptions. Any discussion of the effect of mass, aside from the effect on the principal stresses in the dam, would appear to be a wasted effort since the weight of the concrete in the very small hole cannot possibly affect the stresses to any marked degree.

That the author has gained very little may, perhaps, best be shown by comparing the numerical values obtained by him with those obtained by using Equations (106). At the point on a solid buttress corresponding to the center of the hole in the author's example, the principal stresses are easily obtained[36] from Equations (8) and (22):

$$s_1 = +\,0.0427\ p\ h \ldots\ldots\ldots\ldots\ldots\ldots\ldots (107a)$$

and,

$$s_2 = -\,0.5481\ p\ h \ldots\ldots\ldots\ldots\ldots\ldots\ldots (107b)$$

The angle of the maximum principal stress with the author's X-axis is: $\epsilon = -\,7°\ 38'$; hence; $\theta_1 = \theta - \epsilon = \theta + 7°\ 38'$. From Equations (106) the values given in Table 3 are then obtained and compared with author's values. It will be noted that by the use of the author's extremely unwieldy equations, numerical values are obtained which differ only little from those obtained from Equations (106), and the writer is inclined to believe that the latter are just as "exact" as the formulas given by Mr. Silverman; they certainly are "exact enough" and very much simpler.

FRED L. PLUMMER,[37] M. AM. SOC. C. E. (by letter).—Based on the assumptions defined by Equations (9) the author has developed formulas giving the stresses around circular openings in mass structures. The derivation is presented in a clear and straightforward manner, and illustrates a very skillful use of mathematical theorems. The writer wishes to call attention to the fact that the aforementioned assumptions cannot always be justified, and to question whether, in any case, the designing engineer is warranted in using such complicated formulas when they are developed from assumptions which, at best, can give only a crude approximation of the stresses that will exist in the actual structure.

---

[36] See, also, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), Equations (17) and (21), pp. 1247–1248.

[37] Cons. Engr.; Associate Prof., Structural Eng., Case School of Applied Science, Cleveland, Ohio.

Fig. 12(*a*) shows a buttress similar to the one used by the author in his illustrative example. Obviously, any plane section cut perpendicular to the up-stream face of the buttress, except for the short section, *a-b*, would extend indefinitely into the foundation. The assumptions that the normal stresses on such planes (*c*) are distributed linearly in accordance with Equation (9*a*), and that the shear stresses along such planes (*d*) increase uniformly with the distance from the loaded face in accordance with Equation (9*c*), are obviously far from even a reasonable approximation of the probable stress distribution. On the other hand, the assumption that the direct compression parallel to such planes is constant in accordance with Equation (9*b*) may be more true for planes through *c* and *d*, Fig. 12, than for a plane through *f*.

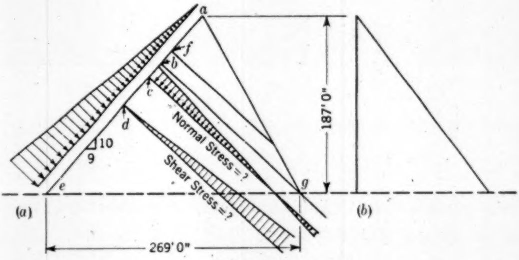

FIG. 12.

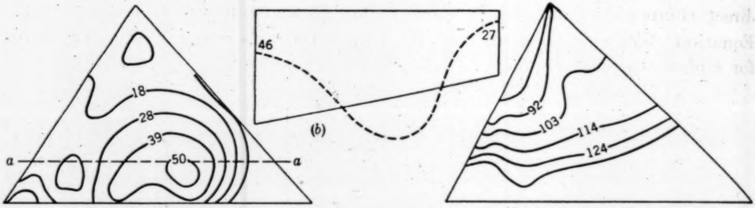
It would seem, therefore, that no formula based on these assumptions could be of any value in studying stresses at any point in the section, *b-e-g*, of this buttress. Since stress distributions in Nature cannot be altered abruptly, it is probable that the stresses along a plane through *f* are very similar to those on a plane through *b*. In consequence, it does not seem likely that the stress distribution assumptions defined by Equations (9), nor any formulas based upon these assumptions, could be properly applied to any part of the buttress shown in Fig. 12(*a*), except possibly a small segment at the top of the buttress.

As the slope of the up-stream face of the section is made steeper and the section more nearly approaches that shown in Fig. 12(*b*), the aforementioned assumptions seem to lead to closer approximations of the actual stress distributions. Even in the case shown in Fig. 12(*b*) however, the actual stress distribution may vary quite materially from that indicated by these assumptions. Such variation may be illustrated by considering the very simple case shown in Fig. 13(*a*), which is drawn from a photoelastic picture showing the variation of maximum shearing stresses in the buttress of Fig. 12(*a*) due to the weight of the buttress itself. The usual assumptions, analogous to those based on Equations (9), would indicate maximum shearing stresses along the plane, *a-a*, varying uniformly from 27 lb per sq in. at the up-stream face to 46 lb per sq in. at the down-stream face as shown by Fig. 13(*b*). The distribution of shearing stresses given by the model is shown by the dotted line. This would indicate that the direct compression stresses caused by the triangular mass of concrete above this section, are not distributed uniformly, but that the intensities are much greater near the middle of the section. This effect has been recognized in many other types of problems.

Fig. 13(*c*) shows the variation of shearing stresses in the same buttress due to the weight of the buttress and, in addition, a water load applied to an area on the up-stream face twelve times as wide as the buttress. In each case, the lines represent contours joining those points where the maximum shearing stresses in the analogous concrete buttress equal the values indicated on the diagrams, the unit being pounds per square inch. In neither case, nor along any plane section, does the stress distribution agree closely with that given by the assumptions defined by Equations (9). On the other hand, Fig. 14 shows a section for which the stress distribution given by the model and that based on these same assumptions agree rather closely on several typical sections and for both dead load, and combined dead and water loads.



(*a*) WEIGHT ONLY (*c*) WEIGHT AND WATER LOAD

FIG. 13.

The writer wishes to emphasize the fact that the preceding statements imply no criticism of the author's mathematical derivation, nor of the resulting formulas. Granting the underlying assumptions, the formulas correctly represent the stress conditions around a circular opening. Unfortunately, many designers of engineering structures have been trained to rely too implicitly on printed formulas and, in consequence, often use such aids without understanding the underlying assumptions and, more important, the resulting limitations of every such formula. The formulas under discussion were originally called to the writer's attention by a young engineer who was applying them to a structure for which they could not possibly give results of any value.

It is important that engineers recognize the fact that openings in massive structures in which the normal principal stresses are all compressive may result in tangential tension stresses near the boundaries of such openings. Obviously, in concrete structures, it is wise to provide steel reinforcement in sufficient quantity, placed so as to resist such stresses properly. Equation (1) indicates how much the tension stress in a bar may be increased due to the presence of a small circular hole. Fig. 15 shows the variation of stresses near a circular opening in an area, the least dimension of which is at least four times the diameter of the hole. In Fig. 15 a uniform compressive stress is assumed to act in the direction of the Y-Y axis. Due to the presence of the hole, tension stresses are created, and the compression stresses are increased as indicated. Formulas developed by A. and L. Föppl[38] give the radial, tangential, and maximum shearing stress at any point, *A*, as:

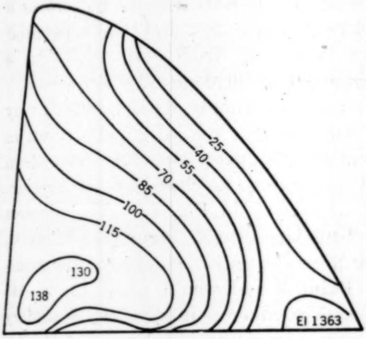


FIG. 14.

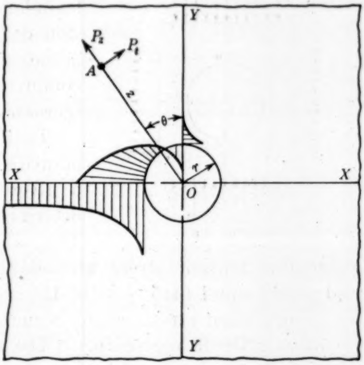

FIG. 15.

$$s_z = \frac{s}{2}\left[1 = \frac{r^2}{z^2} + \left(1 - \frac{4\,r^2}{z^2} + \frac{3\,r^4}{z^4}\right)\cos 2\,\theta\right] \ldots\ldots (108a)$$

$$s_t = \frac{s}{2}\left[1 + \frac{r^2}{z^2} - \left(1 + \frac{3\,r^4}{z^4}\right)\cos 2\,\theta\right] \ldots\ldots\ldots\ldots (108b)$$

and,

$$s_Q = \frac{s}{2}\left[-1 - \frac{2\,r^2}{z^2} + \frac{3\,r^4}{z^4}\right]\sin 2\,\theta \ldots\ldots\ldots\ldots (108c)$$

in which s = the principal stress at *A* if no hole is present (s can act in any direction); r = the radius of the hole; z = the distance from the center of the hole to Point *A*; s_Q = maximum unit shearing stress at Point *A*; and, θ = the angle as shown referred to the direction in which s acts.

If θ is made equal to 90°, Equation (108*a*) reduces to Equation (1) giving the stress distribution along the *X-X* axis. With θ equal to zero, the tangential tension stresses along the *Y-Y* axis may be found. The greatest tension stress occurs at the boundary of the hole and equals in intensity the applied compression stress, *s*. This tension stress decreased along the axis, *Y-Y*, to zero at a point, $r\sqrt{3}$, from the center of the hole.

---

[38] "Drang und Zwang," p. 314.

By integration the total tension for unit width may be found to equal $\frac{-s r}{3\sqrt{3}}$, with this resultant force acting at a distance approximately equal to 1.173 r from the center of the hole. If z is made equal to r the resulting formulas define the variation of stress around the boundary of the hole, indicating tangential tension decreasing in intensity from s to zero as θ is increased from zero to 30°, and then tangential compression increasing from zero to $3s$ as θ increases from 30 to 90 degrees.

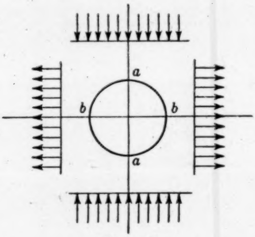

FIG. 16.

To illustrate how simply these relations may be utilized consider that the principal stresses in a given region of a mass structure have been determined, assuming no hole to be present. The values are shown in Fig. 16. The greatest tangential tension stress around the boundary would occur at Point a, and would equal ($445 + 3 \times 15 = 490$ lb per sq in.). Similarly, the greatest compression stress would occur at Point b and would equal ($3 \times 445 + 15 = 1\,350$ lb per sq in.). The stresses at other points on the boundary of the hole can be found in a similar manner by the use of Equation (108b), with $z = r$, the effects of the two principal stresses being computed separately and then combined algebraically. The stress distribution used in this illustration duplicates approximately that which the author found to occur around the hole in the buttress analyzed in his illustrative example.

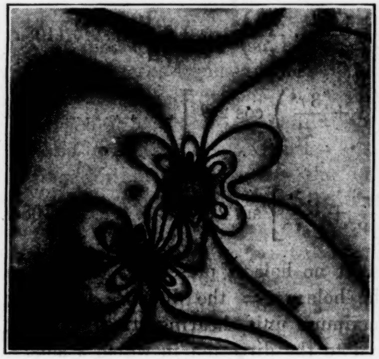

FIG. 17.

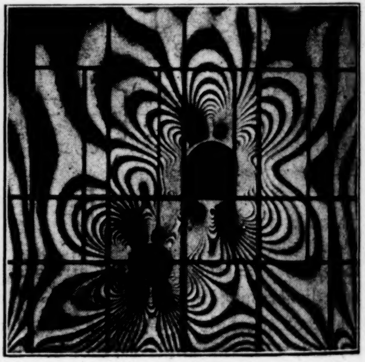

FIG. 18.

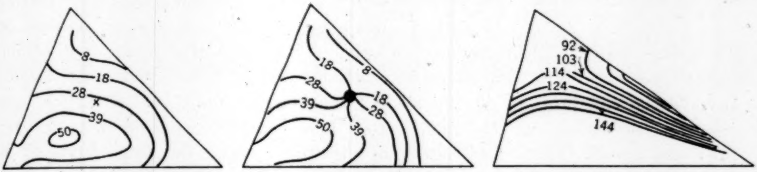
Using the data of the paper, the writer has computed the principal stresses that would act in a solid buttress at a point corresponding to the center of the hole specified by the author. Duplicate computations based on three separate sets of generally accepted assumptions result in values of the major principal stress varying in compression from 300 to 570 lb per sq. in. As indicated previously the value obtained by the author was about 445 lb per sq. in. in compression. In the writer's opinion it is this part of the problem which needs serious study. Moreover, it would seem that designers must look to experimental, rather than analytical, methods.

Figs. 17 and 18 show photo-elastic studies of stress distribution in the region of two openings in both a gelatin and a marblette model of a section of a concrete dam. The writer has found this method of study to be very useful and, in general, more reliable than any purely analytical method which of necessity must be based on simplifying assumptions. Obviously, it would be impractical to derive formulas which would be applicable to the complicated situation illustrated by Figs. 17 and 18. Fig. 19 shows a model study of the buttress analyzed by the author. The scale of the model is too small to determine accurately the stress variation around the circular openings. A large scale model of a part of the buttress would be used for this purpose. However, the models show clearly that the stresses in the region of the hole are quite different from those given by computations based on the assumptions used by the author.



(a) WEIGHT ONLY (b) WEIGHT ONLY (c) WEIGHT AND WATER LOAD

FIG. 19.

The curves in Figs. 14 and 17 and the photo-elastic views in Fig. 18, are taken from studies made in co-operation with the office of the U. S. Engineer Corps, at Huntington, W. Va., and under the direction of Lt. Col. John F. Conklin, District Engineer, and A. L. Alin, M. Am. Soc. C. E., Chief of Design on the Bluestone Project.

I. K. SILVERMAN,[39] JUN. AM. SOC. C. E. (by letter).—In a very constructive discussion, Mr. Mindlin shows that the stresses due to gravity in a solid two-dimensional homogeneous body containing holes involve the elastic constants of the material. His analysis yields Equations (60) which are to be compared with the Equations (34) of the paper. The appearance of the elastic constants in Equations (60) is analogous to their appearance in problems dealing with statically indeterminate systems in the theory of structures. Thus, Equations (34) may be considered to be a solution of a statically indeterminate system by methods applicable only to a determinate system. The maximum difference involved in these formulas from the point of view of pounds per square inch of stress can be determined by using $\nu = 0.18$ for Poisson's ratio. The maximum absolute value of this difference is, $c\, r_h \left[1 - \frac{3 - \nu}{2} \right] = 1.71$ lb per sq in. Practically, System II can be neglected entirely, the effect of mass forces being given by Equations (31). This fact suggests that in making photo-elastic tests for mass forces boundary stresses to be applied at the surfaces of the model could be computed by means of Equations (23), (24), and (25), after the stresses defined by Equations (26) are subtracted. Equations (60) are checked both by Equations (70) in the discussion by Mr. Brahtz and by Equations (77) in Mr. Fedorov's contribution.

---

[39] Asst. Engr., U. S. Bureau of Reclamation, Denver, Colo.

Mr. Vetter presents Equation (106*b*) to be compared with Equations (18) and (31) of the paper, and shows that the numerical results of Table 3 coincide very closely with those given in Table 1. His reference to the "unwieldy" equations of the paper is not clear. Apparently, he is referring to Equation (18) and Equation (31) which give the hoop stresses at $\rho = r_h$ for water and mass, respectively. These equations are of the simplest type to apply. They contain trigonometric terms and terms which involve the constants of the structure; that is, the angle of batter, the location of the center of the hole, etc. They can be applied without any previous knowledge of the theory of elasticity or of the steps involved in their derivation.

Equation (106*b*), which gives the corresponding hoop stresses, involves the following steps: (1) Determination of the state of stress at the center of the hole; (2) determination of the direction of the principal stresses at the same point; (3) determination of the principal stresses, s_1 and s_2; and, (4) substitution of the various values of the argument, θ_1, in Equation (106*b*). Step (4) involves the use of a new set of co-ordinate axes from which the values of θ_1 are to be measured. In the application illustrated in the paper this step involved a rotation of — 7° 38′ with respect to the natural set of axes taken along the sloping face.

For the sake of completeness the equations required for these operations are given for the case of water loading:

$$s_x = \frac{p\,x}{K^2} - \frac{2\,p\,y}{K^3} \qquad (109a)$$

$$s_y = -\,p\,x \qquad (109b)$$

and,

$$s_s = -\,\frac{p\,y}{K^2} \qquad (109c)$$

$$\tan 2\,\epsilon = \frac{2 s_s}{s_x - s_y} \qquad (110)$$

$$s_1 = \frac{s_x + s_y}{2} + \sqrt{\left(\frac{s_x - s_y}{2}\right)^2 + s_s^2} \qquad (111a)$$

and,

$$s_2 = \frac{s_x + s_y}{2} - \sqrt{\left(\frac{s_x - s_y}{2}\right)^2 + s_s^2} \qquad (111b)$$

It is seen that an intimate knowledge of the theory of elasticity is required for the correct application of Equation (106*b*) which is simple in form but complex in use.

Mr. Vetter states that the writer has avoided the necessity for the assumption that the hole is very small as compared with the other dimensions of the body in using Equations (42) to (46). The point of the solution, however, is such that this assumption is not needed. The following fact is responsible for the mathematical solution of the problem; Equation (42), the general solution for plane stress problems in polar co-ordinates, yields stresses according to definitions, Equation (41), which are of the identical form of Equations (10) to (12), inclusive. In applying the method of Filon to an annular disk, the ratio of the outer diameter to the inner diameter is involved. For practical purposes, and in agreement with St. Venant's principle, this ratio is taken as zero, and the assumption is made at the proper point. (See text following Table 2.) That this assumption did not appear in the main body of the paper, as Mr. Vetter points out, is due to editorial exigencies, which required that the greater portion of the mathematics involved be placed in an Appendix. In a general way this assumption is implied in non-mathematical language in the first sentence of the opening paragraph of the section entitled "General Formulas."

Mr. Vetter refers to the paucity of references. Footnote references (3) and (4) were deemed to be sufficient cross-references to all work involving stresses around discontinuities.

Professor Plummer questions the assumption of linear stress distribution as given by the Lévy solution, Equations (8) and (22). Both[40] experiment and theory have shown that this departure from linear behavior is confined to the lower third portion of a triangular dam. The maximum possible discrepancy occurs at the boundaries and has very little effect on the principal stresses involved in the region of the hole. The writer believes that the ordinary engineering theory of straight-line variation is sufficiently accurate for all practical purposes, especially when such complex questions of temperature, shrinkage, etc., are equally involved.

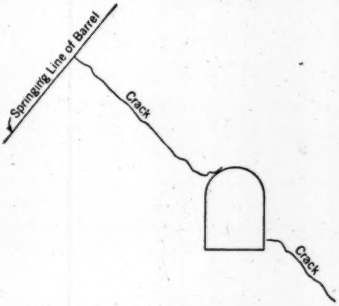


FIG. 20.

Professor Plummer states that his experimental results are quite different from those obtained by using the writer's theoretical equations. Mr. Vetter has shown that comparable results can be obtained by determining the principal stresses at the center of the hole and applying Equation (106*b*). Experiments[41] made at the U. S. Bureau of Reclamation show a very close agreement between experimental and theoretical results. It is not to be expected that the models used by Professor Plummer will give any conclusive experimental results. Probably the maximum size of model possible in a photo-elastic testing apparatus is of the magnitude of 6 in. The diameter of the hole representing a gallery of two one-hundredths of the height would be approximately 0.12 in. The difficulties in measuring stresses around holes of this size are apparent.

[40] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), pp. 489-591; and Vol. 101 (1936), pp. 1258-1259.

The type of model used at the U. S. Bureau of Reclamation consists[42] "of a square slab of plaster celite about seven times the width of the gallery opening. * * * The sides of the square are parallel to the direction of the principal stresses occurring at the center of the area." The slab was roughly 3 ft square.

Mr. Hanna summarizes the formulas in use by designing engineers and describes cracks in dams which he has observed. In a memorandum to J. L. Savage, M. Am. Soc. C. E., Chief Designing Engineer, U. S. Bureau of Reclamation, H. M. Westergaard, M. Am. Soc. C. E., describes cracks observed in dams and mentions a type of crack in buttresses of hollow dams (Fig. 20) which can be explained by the theory as given in this paper. The cracks occur in regions of tensile stress as predicted by Equation (18). In these regions the reinforcement has pulled out, which supports Professor Posey's contention that "the proper placing of steel bars around holes is of great importance."

RECLAMATION AS AN AID TO INDUSTRIAL AND AGRICULTURAL BALANCE

BY ERNEST P. GOODRICH,[1] AND CALVIN V. DAVIS,[2] MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOSEPH JACOBS, M. E. MCIVER, C. S. JARVIS, JOHN P. FERRIS, L. C. GRAY, CHARLES P. WILLIAMS, AND ERNEST P. GOODRICH AND CALVIN V. DAVIS.

SYNOPSIS

The economic pattern that has evolved from the troublesome years of 1929 to 1936 indicates that the future industrial structure will be related intimately to agriculture. Reclamation projects scattered over the Western States can have a profound influence in strengthening this link between the factory and the soil because many of these districts are ideally suited for development as complete economic units rather than as agricultural projects alone. A review of the benefits that may be obtained by co-ordinating industrial and agricultural activities on reclamation projects is presented herein.

The writers have studied this problem from three angles: First, the decentralization of industry; second, the diversification of labor; and third, the co-ordination of industry and agriculture. Part I is devoted to a review of the basic principles of each of these factors. In Part II these principles are applied broadly to an actual project to illustrate the industrial and social growth that could follow the construction of hydraulic works in a given area. These potential benefits are illustrated further in Part III by a more detailed analysis which demonstrates the possibilities of co-ordinating industry and agriculture within one of the irrigation districts that will benefit from the projects. Although the conclusions are based on a specific investigation, they would also undoubtedly apply to many of the new irrigated developments that have been made available by Boulder Dam, and other great water conservation projects.

NOTE.—Published in November, 1936, *Proceedings*.

PART I.—BASIC PRINCIPLES

THE DECENTRALIZATION OF INDUSTRY

Historical.—Industrial congestion in thickly populated cities began with the domestic system long before the industrial revolution. In the early days employers furnished tools, equipment, and housing to workers, who conducted most of the manufacturing operations within their own homes.

The domestic system led to the establishment of the manufacturing towns and cities and these, later, furnished the labor supply for the factories which sprang up during the industrial revolution. The first commercial steam engine manufactured by James Watt in 1776—the engine that was really to begin the industrial revolution—started factories on the road to overgrowth. Steam power had to be used at its source; therefore, great size and economy of operation went hand in hand.

A continued increase in the population densities of industrial cities accompanied the overgrown factories that followed the industrial revolution. Many of the wretched social conditions, that the nation is now striving so desperately to correct, have been inherited from this particular stage of economic evolution. The industrial worker of the city, with his abilities narrowed by mass-production methods, has no alternate means of livelihood during "shut-downs."

The mobility of electric power stands in sharp contrast to the fixed nature of steam power. Electric power, therefore, will be an important factor in the breaking down of great industrial units into smaller and more efficient production plants. Long-distance electrical transmission can make it possible to distribute these smaller plants over rural areas in locations where co-ordination with agriculture may be effected.

Principles and Trends.—Decentralization means the transfer of industry from the great factories of the industrial city to smaller plants in suburban or rural areas. In some cases both workers and plants are being relocated; in others, branch plants are being established.

The purposes of decentralization are: (1) To build partly self-sustaining areas; (2) through the establishment of controls, to balance production and consumption within these areas; (3) to lower greatly the cost of distribution; (4) to increase living standards by decreasing costs and by increasing both production and consumption; (5) to eliminate the evil effects of mass-production methods on industrial workers by the diversification of labor; and (6) to create better social conditions by moving workers and their families away from congested industrial districts and giving them the many advantages incidental to suburban or country life.

Industry is moving away from the congested industrial centers of the East. Evidence of this fact may be found in the "Industrial Census" which shows that the center of gravity of manufactures moved 329 miles westward between 1849 and 1919. During the thirty years between 1899 and 1929, in the areas of "primary concentration" (the big industrial cities), the number of wage jobs per 1 000 population fell from 124 to 106. In the areas of "secondary concentration" (the outlying fringes of the great manufacturing centers and the smaller industrial towns), the corresponding decrease was less—from 106 to 105. Throughout the remainder of the United States, or the rural areas, however, the number actually increased from 34 to 45.

Other evidence of the trend of industry to locate in suburban or rural areas may be found in the statistics of plant movements between 1927 and 1929. During that period, 287 industrial plants, affording 18 599 wage jobs, were moved. Of this number 5 654 employees were moved away from the big cities, 1 933 going to the smaller cities and 3 721 going into the country or to small rural towns.

Future rural relocations will generally be accompanied by decreases in the sizes of production units. Recent studies of the economic sizes of manufacturing plants have shown conclusively that relatively small production units give the most satisfactory results. L. W. W. Morrow, Editor of the *Electrical World*, presented the following significant facts[3] relating to this subject.

An investigation of the machine tool industry made in 1932 shows that the economic size of a plant is one that uses 80 000 to 100 000 man-hr per yr; yet 96½% of the plants in this industry have a greater productive capacity. Studies of three other industries show the same facts—that is, a relatively small production unit is most economical; but at present the greatest productive capacity is found in the larger plants.

In 1933 a certain manufacturer supplied the national market from three plants and manufactured eight products. To-day, this manufacturer has forty plants, one in each market area, and sells sixty-five products through one sales organization. Present earnings are highly satisfactory.

As a result of his studies, Mr. Morrow concluded that:

> "An analysis of the growth of manufacturers shows that small plants or branch plants are being built in each market area and, on the whole, these are more prosperous than the large plants supplying the national market because they restrict their activities to sales in these local areas. The manufacturers who make one product for the national market with a single production plant in one location are suffering the greatest losses."

Mr. Henry Ford, a pioneer in the decentralization movement in the United States, has long advocated both the diversification of labor and a return to the small factory. Extensive experiments in industrial decentralization have been conducted in the vicinity of Dearborn, Mich., with the results summarized in the following statement by Mr. Ford[4]:

> "Ten years ago we started seven village industries on small water power sites, all within twenty miles of Dearborn, our purpose being to combine the advantages of city wages with country living. The experiment has been a continuous success. Overhead cost has been less than in the big factory, and the workers would not hear of going back to the city shops."

Mr. Ford began to acquire land for this experiment several years ago. To-day (1936), his holdings for this purpose embrace 40 000 acres. Farms grouped in large tracts—the largest is 10 000 acres—are tilled on the co-operative plan. Many Ford parts, including starters, lamps, gages, and drills are produced in fourteen small plants located in rural areas within fifty miles of Detroit, Mich. In 1934, these plants produced $8 000 000 worth of parts and tools, employed 2 500 workers, and paid $1 500 000 in wages to these small town workers.[5]

---

[3] "Balancing Technocracy" *Electrical World*, January 14, 1933.

[4] "Farm and Factory," *New York Times*, June 3, 1932.

From the foregoing it is evident that decentralization is no longer an academic question for industry; experience has proved this to be a beneficial and constructive measure. No clearer picture of the possibilities of decentralization could be obtained than that given by the Secretary of Agriculture[6]:

> "The ten million unemployed plus the five million living on land which can never be farmed are a continuing menace to the established industry and agriculture of the United States. To solve it means decentralized industrial planning relative to land. If the heads of our two hundred leading corporations were to take into account the full significance of paved roads, autos, trucks, high line electricity, and the increased happiness of human beings close to the land, might they not enthusiastically start a decentralized, industrial, self subsistence homestead program on a scale which would jerk us out of the depression for years to come"?

THE DIVERSIFICATION OF LABOR

Need of Diversification.—The rate of increase of unemployment has kept pace with technological progress. Each year occupational obsolescence has been sending increasing numbers of men to the "scrap heap." Consider, for example, the following unemployment statistics for the relatively prosperous years of 1923 to 1929, inclusive:

Year:	Unemployed:
1923	1 500 000
1925	1 775 000
1927	2 000 000
1929	3 000 000 to 5 000 000

The reasons for this steady increase in unemployment are suggested by the following tabulation[7], which shows, for certain commodities, the increases in production and the decreases in labor force for the years 1923 to 1927, inclusive:

Industry	Increase in production	Decrease in labor force
Oil refineries	84%	5%
Tobacco	53%	13%
Meat	20%	19%
Railroads	30%	1%
Building (Ohio only)	11%	15%
Coal	4%	15%
Steel	8%	9%
Cotton	3%	13%
Lumber	6%	21%

[5] *New York Times*, September 8, 1935.

[6] "New Frontiers," by the Hon. Henry A. Wallace.

[7] From "An Introduction to Problems of American Culture," by Professor Rugg, pp. 182 and 194.

Instances of unemployment due to technological improvements are legion and space permits only typical examples to be included herein. Improved mining methods have greatly increased the output per worker and, consequently, decreased the number of workers. During the past thirty years the output per worker in soft coal mining increased 60%, in copper mining, 100%, and in the mining of ore, 200 per cent. These increases in efficiency resulted in the permanent unemployment of 64 000 men, engaged in the extractive mineral industries, in the boom year of 1929[8].

The foregoing data present a better picture of occupational obsolescence than could be obtained from similar statistics for the depression years of 1930 to 1935. The abnormal situation in these years was influenced by so many factors that it would be impossible to segregate the effect of any single cause of unemployment.

Probably the most startling development in occupational obsolescence since 1929 was revealed in 1933 by the report of the Henderson Committee[9] in the automobile industry. It was stated therein that keen competition has speeded this industry to a pace considered too fast for men of forty and that, in some instances, 19 men do the work of 250 by contrast with 1929.

Other findings of the Henderson report were of an equally surprising nature; for example, in one plant a door is now made in two stamping operations. In 1929, a door manufactured by this same plant had twenty-six different parts and required several times as many men to make it. Body framing which cost $3.00 in 1929, now (1936) costs $0.30. It cost $0.60 to hang one door in 1929; it cost $0.9 to hang four doors in 1935. Body trimming cost $12.00 in 1929; it costs $4.00 to-day.

The Henderson Committee report stated:

> "Less than five years ago a well known auto manufacturer finished 100 eight cylinder motor blocks on a given line-up with 250 men. To-day the same line-up finishes 250 motor blocks, with 20% more operations with only 19 men. Men were paid $13.20 per hundred blocks five years ago and through the use of tungsten carbide tool tips men now do the same work for $5.20."

It was shown that single machines introduced in factories are automatically removing from 100 to 250 employees.

Many other instances could be cited; the foregoing, however, will serve the purpose of this paper. Without turning to other illustrations of the present trend, it is obvious that two conclusions may be drawn regarding the effects of mass-production methods on a worker: First, his calling may be swept away almost without notice by technological changes, leaving him without alternate means of support; and second, mass-production methods are narrowing to such a degree that little or no mental labor is required. New industries, to absorb the workers thus eliminated from the progressive industries, will doubtless eventually be evolved, but during their development the men and their families suffer greatly.

---

[8] "America's Capacity to Produce," p. 155.

[9] *New York Herald-Tribune*, February 7, 1935

The best quick remedy for this situation lies in the diversification of labor. Productive employment in work supplementary to that of the factory must be planned to fill the extended periods of idleness that have accompanied each depression. Although this need has been recognized for many years, it has been only recently that a few industrialists have taken steps to provide some alternate employment during the idle time.

Experiments in the Diversification of Labor.—Obviously, many kinds of work could be planned on a part-time basis. A return to the soil, however, offers the easiest and the most direct method of capitalizing idle hours. This fact was recognized by a group of progressive manufacturers who were trying every available means of coping with the unemployment problem during the depression. With a view, at least, toward keeping workers supplied with food, suitable tracts of land adjacent to the plants were purchased or leased and prepared for planting. Part-time and idle employees then cultivated these tracts and received in return for their labor either the produce of their individual plots or a proportionate share of the yield if the tracts were operated on the co-operative plan.

The experiences gained in administering these agricultural projects as supplements to industry bear a direct relation to this investigation. These experiences enabled the writers to base their analysis on actual operating data rather than on assumptions.

In giving consideration to agriculture as an alternate occupation for industrial employees, many questions arise at once. For example, what classes of labor (skilled or common) adapt themselves most readily to this plan? Would skilled workers care to divide their time between the farm and the factory? Assuming that these workers are inclined to try the experiment, would they be qualified by temperament to grasp an entirely new occupation? What is the cash outlay required of an industry to put such a plan in operation, and what are the returns? Is the worker compensated adequately for his hours of agricultural work? What time must be devoted to such work and how much land is required per dependent? What is the best plan of management? What educational measures are necessary?

In order to obtain answers to these questions the writers' studied in detail the results obtained in eight experiments in industrial co-operative gardening. Space limitations permit only two of these to be described herein.

EXAMPLE 1

General Plan.—During 1931 and 1932 more than 500 former workers of a certain company were unemployed and many others were working only part-time due to an unavoidable curtailment of production schedules. In order to minimize the monetary loss and the physical suffering caused by extensive lay-offs or part-time employment, the Company aligned itself with the municipal government and the civic relief organization. A co-operative farm plan was selected as the most practical solution of the problem.

Consideration was given to both the individual-plot and the mass-production methods of operation. Although no precedent was available for the latter, the management decided that mass-production methods were equally applicable to gardening and manufacturing. The satisfactory results that followed the adoption of this policy are particularly significant.

Early in May, 1932, leases were secured on three tracts aggregating 275 acres in a river valley five miles from the factories. Of this land, 200 acres were tillable. The Employment Manager, was made Director of the project and an engineer with extensive agricultural and industrial experience, was engaged to prepare the detailed plans and to supervise the actual field operations. Plowing was begun as rapidly as the land could be cleared of brush and débris and made ready for cultivation. Drainage ditches, culverts, a small headquarters building, and sanitary facilities were then provided. By May 12, 2 000 early cabbage plants, 2 000 tomato plants, and several bushels of onions had been set out and these were followed immediately by the planting of other vegetables.

The labor-rotation plan, based on the individual working one 8-hr day per week, was followed. Schedules were based on an anticipated total of 150 000 man-hr, embracing 750 men over the 25-week period. Actually, a total of 936 men took an active part in the gardening. When all planting was completed the gardens had the acreage in crops shown by Table 1.

TABLE 1.—ACREAGE OF INDUSTRIAL CO-OPERATIVE GARDEN PROJECT, EXAMPLE 1

Crop (1)	Area, in acres (2)	Crop (1)	Area, in acres (2)	Crop (1)	Area, in acres (2)	Crop (1)	Area, in acres (2)
Potatoes	63.0	Bush and pole beans	8.1	Peppers	2.0	Onions	0.6
Navy beans	40.0	Turnips	7.6	Carrots	1.2	Swiss chard	0.5
Field corn	25.5	Beets	3.8	Kale	1.1	Radishes	0.4
Sweet corn	11.0	Pumpkins	3.0	Summer squash	1.0	Mustard	0.3
Tomatoes	9.5	Peas	3.0	Spinach	1.0	Lettuce	0.2
Cabbage	8.5						

Before planting the potatoes, consultations were held with the staff of the Experiment Station at the State University and with the champion potato grower of the State, a down-State farmer, and 1 300 bushels of certified seed potatoes were obtained from a reliable source.

Less than 25% of the workers had a true farm background. Although this general lack of gardening experience caused the work to progress rather slowly at first, the workers familiarized themselves with their new occupation rapidly. The instructions of the supervisor were grasped quickly and in a few weeks a fair degree of skill in farm work had been developed.

No records were kept of the percentages of the classes of labor (that is, skilled or unskilled), or of the relative performance of each class. It was found, however, that both classes readily adapted themselves to the program. The results of this experiment show conclusively that industrial workers can readily diversify their labor. They represented practically every production division of the factory, and although, their normal occupations had been limited to a highly developed system of mass production, they fitted into the garden plan admirably.

Those who enrolled in the garden force realized the importance of the opportunity provided them in the farming project and entered into the spirit of the work at hand as if they were compensated in money rather than in produce. Former employees, whose individual factory records were above the average, in the majority of cases also proved to be the best "farmers," substantiating the belief that mass-production methods and training can be applied successfully to an agricultural enterprise.

Costs.—The total average investment was about $50 per acre cultivated, as developed from the following itemized summary:

Item	Cost
Plowing, harrowing, planting, including labor, tractor rental, team hire, fuel, mechanical sewer, planter operation, and replacement parts	$1 900
Transportation of farm workers and materials, including use of trucks and passenger bus	1 550
Supervision (Farm Superintendent, part-time truck driver, and incidental specialized labor)	1 400
Spraying materials and equipment	1 100
Seeds, including seed potatoes	1 000
Fertilizer	800
Leases for land	750
Culverts, drain-tile, lumber for headquarters and distribution building, rental of storage trailers, road maintenance	250
Small equipment—tools	150
Incorporation and workmen's compensation	125
Miscellaneous	225
Total	$9 250
Interest, 6 months at 5%	231
Total investment	$9 481

$$\text{Investment per acre} = \frac{\$9\,481}{191.3 \text{ acres}} \doteq, \text{ say, } \$50$$

Return on Investment.—The man who worked 1 day per week on the gardens during the season, without extra work or absence, received the items listed in Table 2, totaling in weight more than 1 ton. This quantity of vegetable food is sufficient to take care of a family of five for nine months. The total value of the produce was easily double the amount invested.

TABLE 2.—GARDEN OUTPUT PER MAN, EXAMPLE 1

Produce	Unit	Quantity	Produce	Unit	Quantity	Produce	Unit	Quantity
Potatoes	Bushels	22	Summer squash	Pounds	31.5	Cayenne peppers	Dozen	16
Cabbage	Pounds	127	Rolled oats	Pounds	25.0	Sweet corn	Dozen	10
Tomatoes	Pounds	98	Greens	Pounds	23.0	Green onions	Dozen	7
Corn meal	Pounds	95	Pumpkins	Pounds	10.0	Hot peppers	Dozen	7
Turnips	Pounds	96	Peas	Pounds	8.0	Carrots	Dozen	4
Navy beans	Pounds	75	Kale	Pounds	5.0	Beets	Dozen	3
Green beans	Pounds	69	Dry onions	Pounds	1.0	Sweet peppers	Dozen	2

The efficiency of operation rapidly increased during the succeeding years. Although employment during 1934 had improved to such an extent that a continuance of the gardens was not necessary, the management felt that the experience was of sufficient value to continue with the work. The area cultivated was increased to 300 acres. The investment amounted to about $20 000, or $66 per acre. The value of the crop harvested and distributed, however, was $60 000, or approximately double the amount per acre of the 1932 harvest.

EXAMPLE 2

Another successful industrial gardening project, operated during 1932, 1933, and 1934 may be discussed as Example 2. About 90 acres of land were rented near the plant for gardening purposes and, in addition, employees were encouraged to cultivate individual gardens.

An agricultural expert was placed in charge of the entire project. Aside from the land and supervision, the Company furnished fertilizers, plowing and harrowing, all seeds and plants, and spraying and spray materials. Seeds and plants only were furnished to those with home gardens. The plant gardens were laid out in plots of 50 by 100 ft, with suitable spaces between lots for paths and driveways. This plan gave centralized operation, combined with the advantages incidental to the cultivation of individual plots. Planting schedules for each plot were planned with a view to providing good substantial food and a well-balanced diet.

Each plot holder was required to sign an agreement which set forth the obligations of both the Company and the gardener. The Company agreed to loan the plot, prepare the soil for planting, furnish the seed, and supervise the planting. The gardener agreed to cultivate the land and keep it free from weeds to the best of his ability. In return for this service the vegetables grown on the land became the sole property of the gardener, except in cases where willful negligence was evident. In this event, the Company reserved the right to revoke the agreement.

The employees on a part-time basis took a keen interest in the gardening work and readily grasped the opportunity to take part in the enterprise, once its advantages became evident. The number of plant gardens and home gardens for each year of operation were as follows:

Year	Plant gardens	Home gardens
1932	345	655
1933	587	813
1934	588	833

About 60% of the workers operating these gardens could be classed as skilled and the remainder as unskilled. Both classes were surprisingly proficient in gardening after the brief instruction period. As in the case of Example 1, the industrial employees who were most proficient in the plant obtained the best results with their gardens.

Accurate cost records were kept during 1933 and 1934 in order to determine the return on the investment. Actually, the gardeners, during these years, received vegetable produce equal in value to between five and six times the total cash outlay. Aside from the monetary value of the product, other benefits were reflected in the improved health of the workers and the close relation that existed between the Company and the employees. The social value of this work in keeping idle hands and minds occupied and in supplying wholesome foods cannot be over-estimated.

Education as well as strict supervision is essential to the success of such a venture. In the beginning the Company had talks about gardening by a County farm adviser and agents of the State Department of Agriculture. Canning demonstrations and individual instruction in the care of produce for winter saving were given. Educational measures were directed toward developing a love of the work concurrently with gardening skill. Efforts in this direction were highly successful.

SUMMARY OF EXPERIENCES WITH THE DIVERSIFICATION OF LABOR

The foregoing, together with the other experiments studied by the writers, lead to the following conclusions:

(1) The occupations of both common and skilled labor may be diversified successfully.

(2) Without exception, agriculture has been selected as the most satisfactory alternate occupation to industrial work.

(3) The most efficient factory employees generally obtain the best results from their garden plots.

(4) With a relatively high yield about 0.25 acre is necessary to provide a family of five with vegetable produce for the greatest part of a year. More land per worker is necessary if the soil is unsuited to intensive farming.

(5) The co-operative plan (that is, all the gardens centralized in one large plot) lends itself to the most efficient management. Mass-production methods may be applied to gardening as well as to manufacturing if this plan is adopted. The costs of plowing, harrowing, planting, and harvesting are reduced to a minimum if the gardening activities are conducted at one place. The principal disadvantage of operating one large plot on a labor-rotation basis is that workers may not have the pride or interest in their work that they would if they were responsible for the sole care of an individual garden. This may be overcome by adopting the plan of dividing the central plot into sections and assigning each section to individual workers (see Example 2).

The cultivation of small gardens adjacent to employees' homes is to be discouraged unless the workers or members of their families are skilled gardeners. This plan has produced only indifferent results as the costs of company operation and management are necessarily much higher than those for centralized plots.

(6) The service of a skilled agriculturist is absolutely essential. Few workers have the gardening experience that is required to insure them an adequate return on their efforts, therefore, additional educational measures are necessary. Lectures, educational bulletins, and planting schedules must be supplemented with individual instruction if the project is to be successful.

(7) Centralized storage facilities must be provided and arrangements made for distributing the produce.

The experiments outlined in the foregoing items do not indicate completely the possibilities of labor diversification. Most of these projects were emergency measures and had to be planned on a subsistence basis only. Regardless of this fact important lessons were learned and there now exists sufficient actual experience to state with certainty that labor diversification in connection with manufacturing operations could be both practical and profitable.

Tangible evidence has been presented to show the benefits that could be derived from both industrial decentralization and the diversification of labor. Nothing has been introduced, thus far, to show the improvements that could result from co-ordinating the operations of adjacent agricultural and industrial developments. The following two specific examples relating to irrigated areas show conclusively that economic conditions improved definitely after the introduction of industrial plants.

The Co-Ordination of Industry and Agriculture within Irrigation Districts

Yakima Valley, Washington.—Industries engaged in the processing of agricultural products followed irrigation development in the Yakima Valley. These industries consist of flour and feed mills, alfalfa mills, fruit dehydrator plants, fruit canning plants, meat packing plants, and various other types of plants for the packing, storing, handling, and distribution of crops. The canning plants alone employ approximately 3 000 annually for about 4 months and the dehydrating plants employ 800 to 1 000 for approximately 6 months.

The Federal Government has expended mostly in Yakima County or in irrigation projects approximately $33 000 000. As a result of these projects and their subsequent industrial development, the population of Yakima County increased from 13 462 in 1900 to 77 402 in 1930. During this same time the population of Yakima City increased from 3 154 to 22 101. The assessed valuation of the County has increased from $25 004 000 in 1900 to $233 041 000 in 1930, or almost tenfold.

Obviously, these benefits have been realized through agriculture, as a population base, being followed by factories for the processing of farm products.

Sugar Production in Sidney, Mont.—An outstanding case illustrating the improvement in the economic status of an irrigation district that follows the introduction of industrial plants may be found at Sidney, Mont. The Lower Yellowstone Irrigation Project was not successful as an agricultural venture alone. For a period of ten years the farmers of this District were faced with severe economic difficulties, with the result that water charges were defaulted.

In 1925 a sugar factory was constructed at Sidney which is centrally located in the Valley. At this time, few of the farmers understood the raising of sugar-beets and, in consequence, only about 50 000 tons of beets were produced annually within the District. There has been a gradual growth of the industry, however, and, in 1935, the growers tributary to the Sidney factory produced approximately 200 000 tons, yielding a return to the farmers of approximately $1 500 000. As a result of linking the manufacture of beet sugar to the agricultural production of the Lower Yellowstone Irrigation Project the farmers of this District are now in good financial condition; many, in fact, are increasing their land holdings.

In the connection with the growth of sugar-beets the District also maintains a substantial live-stock development. During 1935, approximately 150 000 head (including lambs, sheep, and cattle) were fed for the market. This large feeding program is made possible by the by-products from both the factory and the farm. Beet tops and beet pulp and molasses make excellent foods in addition to hay.

The successful growing of sugar-beets calls for the rotation of crops on the farms. Alfalfa, the principal rotation crop, provides an ample quantity of hay for feeding purposes. Combining a sugar-beet and live-stock program has produced increased yields of all other crops grown in rotation with sugar-beets. Feeding of livestock is producing an abundance of manure which, through return to the soil, is gradually building up the fertility and yield of the farms.

PART II.—POTENTIAL INDUSTRIAL GROWTH OF CALIFORNIA RELATED TO CENTRAL VALLEY PROJECT

IRRIGATION AS A BASE FOR WESTERN INDUSTRIAL DEVELOPMENT

Much of the land that will be made irrigable by the construction of hydraulic works in the Western States is adjacent to extensive markets for manufactured products. As these markets are now (1936) only partly supplied by local manufacturing establishments, opportunities exist for the profitable expansion of many industries in the Western States. This situation is especially favorable for decentralized industrial planning in relation to the land.

The benefits that would result from such an arrangement are obvious. Irrigation districts would benefit by having many of their products utilized by adjacent manufacturing plants. Hides, cotton, wool, cereals, sugar-beets, and fruits and vegetables are only a few of the agricultural products that could be processed by adjacent industries. In addition, these irrigation districts would benefit by having a substantial portion of their lands operated by industrial employees on a co-operative basis. This would tend to check the over-production of agricultural products on irrigated areas as the products of the co-operative gardens would be consumed principally by industrial employees. A third benefit would be the tremendous increase in population that could be supported by the land.

Industry would be likewise benefited by co-ordination with agriculture. The labor supply would be more stable and more efficient than in crowded urban locations. Industrial employees would have a "back-log" of agricultural employment and, therefore, would not face serious hardships in the event of a factory shut-down. An abundant supply of cheap power is available in most irrigation districts. These advantages, together with nearness to markets and sources of raw material supplies should offer an incentive to many industries either to relocate their factories or to establish branch plants on projects that are adaptable to co-ordinated industrial and agricultural operations.

The large potential markets that now exist adjacent to recently developed irrigation areas would absorb most of the manufactured products at first. As the projects were settled additional markets would be developed in the immediate vicinity of the manufacturing plants. This would give opportunity for an industrial growth in proportion to the increase in population. This process could continue until the land had been fully developed.

Not only would agriculture and industry in the immediate vicinity of the irrigated areas be benefited by co-ordination, industry in all sections of the country would be helped by the extensive construction program and the additional manufacturing equipment that would be required by industrial decentralization.

The truth of the foregoing statements may best be illustrated by a detailed analysis of a selected irrigation project, the Madera Irrigation District in California, which is suitable for combined industrial and agricultural operations. It is impossible, however, to confine the investigation to the Madera District alone; it is first necessary to consider some of the industrial and economic aspects of both the State of California and the Central Valley Project.

For the purposes of this investigation the State of California was considered as a single-market area. An analysis was then made to determine the opportunities for industrial expansion that existed within the boundaries of this area in 1929. After this information was compiled, the capacity of the Central Valley Project to absorb a program of decentralized industrial development was studied broadly. A proportional part of the potential industrial growth for the entire State was then allocated to the district investigated. This consisted of a selected group of industries for which the location factors in the vicinity of Madera were favorable. It is not meant to imply that the Madera District offers the most favorable location in California for the industries selected. It was beyond the scope of this investigation to do more than to apply principles to a specific area. Similar analyses for other districts should indicate whether they too are suitable for combined industrial and agricultural development.

POPULATION GROWTH RELATED TO LAND DEVELOPMENT

The rate of industrial development has been found to bear a definite relation to population growth.[10] Population studies, therefore, are of primary importance in this investigation. In predicting California's future population sight must not be lost of the fact that a substantial part of the high rate of increase during past years has been due to immigration from other States and from abroad. More than 46% of the people now living in California came there during the past decade. The relationship between that part of the population born in California and the total for the State is shown by

---

[10] "Amended Application to Federal Emergency Administration of Public Works," p. 87.

Fig. 1(*a*), which also shows the forecast of population growth from 1932 to 1970, used by the Water Project Authority of the State of California as a basis for the growth curve of future increases in the area of irrigated lands Fig. 1(*b*).

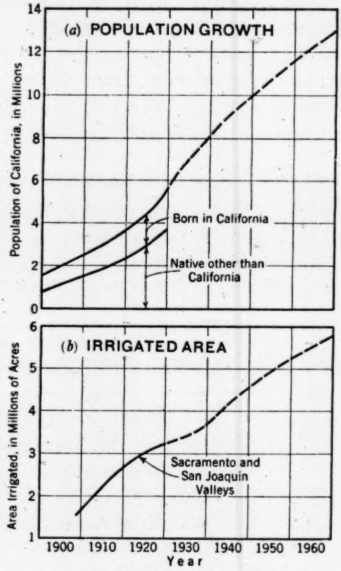

Fig. 1.—Past and Anticipated Growth of California

Agricultural Development

The total cropped area of the State is 8 390 000 acres.[11] Of this area, 4 746 000 acres, or about 57%, is irrigated. The irrigated lands of California, comprising 24% of the entire irrigated area of the United States, are among the most productive in the country. In 1929, California ranked eighteenth in the States of the Union in cropped area, second only to Texas in gross income from crop production. The per capita income of farm population, however, is greater for California than that for any other State.

Industrial Pattern of California

Industry has grown rapidly in California, responding to the westward movement of the center of population. From 1914 to 1929, the value of manufactured products increased 330% and the value added by manufacture, 410 per cent. In each case, this rate of increase was nearly twice that for the United States as a whole.

The 1929 industrial census for California does not present the distorted values that would be given by statistics compiled during the depression years. This investigation, therefore, presents both a cross-section of California industry in 1929 and a reconstruction of the opportunities for industrial expansion that existed in that year. As industrial development has not kept pace with population growth during the depression years there is, in 1936, an even greater opportunity for new industrial development in California than that indicated by the 1929 statistics.

The average value of industrial products per capita is nearly the same for the State of California as it is for the entire country. The following comparison of these values for the years 1929 and 1931 indicates the abnormal situation that existed in 1931 after the depression was well under way:

Description	1929	1931
Total Value of Industrial Products:		
For the entire United States	$70 435 000 000	$41 350 000 000
For California	3 103 000 000	1 985 000 000

---

[11] "Permissible Economic Rates of Irrigation Development in California," *Bulletin*, Univ. of California, p. 38.

Description	1929	1931
Value of Industrial Products per Capita:		
For the entire United States	$577	$336
For California	565	330

A superficial examination of the foregoing statistics would seem to show that California was producing at least its proportionate share of the nation's manufactured goods and that little opportunity existed for profitable industrial expansion in 1929. A detailed study of California's manufactured products, however, shows that the picture is distorted greatly by several industries that serve a much larger population than that of the State. For example, in 1929, the industries in California engaged in the canning and preserving of fruits and vegetables served nearly 36 000 000 people on a proportionate basis; the motion picture industry served 85 500 000 people, and the petroleum refineries served 22 500 000 people.

The total value of the products of these three industries was $834 612 000 for the State of California and $3 574 000 000 for the entire United States. If these sums are deducted from the total value of all industrial products shown in the foregoing list it is found that the values of the remaining products per capita were $407 for California and $547 for the entire United States. These averages show conclusively that the majority of the industries in the State were not sufficiently developed to supply their adjacent markets.

The principal industrial areas in California are the Los Angeles District and the San Francisco-Oakland District. Fig. 2 shows the extent of each district and its relation to the Central Valley Area. Table 3 which gives the industrial characteristics of each of the principal districts, and of the remainder of the State, reveals that industry in California has followed the usual course; the greatest industrial concentration is found in the areas of greatest population density. This tendency of industry to follow its markets would not be altered by the adoption of an industrial decentralization program in connection with the Central Valley Project. Actually, decentralized planning would result in a broadening of this same policy. Many of the irrigated dis-

tricts of the Sacramento and San Joaquin Valleys are sufficiently close to the thickly populated areas to be satisfactory for both industrial and agricultural development. Furthermore, a co-ordinated industrial and agricultural program would enable these valleys to support a much greater population density than that which could derive a living from agriculture alone. The distribution of industries throughout the Central Valley therefore, would have a centripetal effect on their respective market areas. Not only would these industries be situated favorably, as far as the existing potential markets are concerned, they would also have the ultimate result of creating important new markets which would develop inwardly toward the factories as focal points.

TABLE 3.—CHARACTERISTICS OF PRINCIPAL INDUSTRIAL DISTRICTS IN CALIFORNIA

Industrial district	Population in 1930	Area, in square miles	Population per square mile, in 1930	Persons engaged in industry in 1929	Total value of products in 1930
Los Angeles	2 209 000	4 115	537	146 000	$1 319 000 000
San Francisco–Oakland	1 307 000	2 464	530	114 000	1 166 000 000
Remainder of State	2 161 000	149 073	14.5	102 000	618 000 000
Total	5 677 000	155 652	36.4	362 000	$3 103 000 000

INDUSTRIAL SURVEY FOR CALIFORNIA

In order to get a true concept of the deficiency of capacity of the California manufacturing concerns in 1929, it is necessary to make a detailed study of each of the 327 industries classified by the industrial census. If the population served by each industry in the State is computed from the census statistics it is possible to establish for each product the potential markets that exist within the State boundaries.

The most satisfactory method of estimating the population served by each industry is based on the average values of manufactured products per capita; for example, the total value of the products in 1929 of the boot and shoe industry was about $966 000 000 for the entire United States; the average value of product per capita, based on a population of 122 000 000, was $7.92. For the same year the total value of the products of the boot and shoe industry in California was $3 095 000. Dividing this sum by the average value of $7.92 per person gives a total population of 391 000 served by the California factories. The difference between the population of the State (5 500 000 in 1929) and the population served by the industry is 5 109 000 persons who purchased shoes that were manufactured outside the State. Further analysis, including estimates of the population per establishment and the employees per establishment, indicates that 56 additional average shoe-manufacturing establishments, employing a total of 9 400 persons, could have been established in California in 1929. Table 4[12] shows the results of an analysis, similar to the foregoing, for each industry that could have been expanded in California in 1929.

---

A summation of the deficiencies computed in Table 4 shows that in 1929 the value of products manufactured within the boundaries of California could have been increased by about one-third, or approximately $1 000 000 000, if the needs of the population within the State had been served by local manufacturing establishments. If California industries had taken advantage of this opportunity 1 742 new plants, employing more than 164 000 persons could have been established. Perhaps a clearer way of visualizing these deficiencies is to state that an additional industrial development, nearly equivalent in size to that in either Los Angeles County or in the San Francisco-Oakland District, could have found profitable markets within the State of California in 1929.

THE CENTRAL VALLEY PROJECT

The industrial deficiencies summarized in Table 4 are related intimately to the inadequate water supplies of the southern part of the State. This condition will be corrected by the Central Valley Project.

The principal construction features of this project (see Fig. 2) are the Kennett Dam and power plant, the Kennett transmission line and sub-station, the Keswick Afterbay Dam and Reservoir, the Keswick power plant, the Sacramento-San Joaquin Delta cross-channel, the Contra Costa conduit, the Friant Dam and power plant, the Madera Canal, the Friant Kern Canal, and the San Joaquin pumping system.

LOCATION FACTORS

In order to select a suitable location for each of the industries listed in Table 4, consideration must be given to the following factors: (1) Water supply; (2) proximity to supply and quality of raw materials; (3) location of markets for the finished product; (4) transportation costs; (5) State and local taxes; (6) power costs—hydro-electric, oil, and coal; (7) sources of labor supply, labor rates and attitude of those in control of State and local politics in controversies between labor and capital; (8) living costs; (9) climatic conditions and general health; (10) social conditions; and, (11) availability of industrial sites.

The relative weight of each of the foregoing factors will vary greatly with the particular industry; for instance, industries employing large numbers of men are certain to rate labor factors high. Plants producing heavy or bulky products will place special emphasis on transportation costs and proximity to markets. The development of such industries within certain sections of the Central Valley will be made economically possible by the low-cost water transportation that will follow the channel improvement of the San Joaquin and Sacramento Rivers. Water supply is a particularly important factor in determining the location of breweries, creameries, and packing plants.

It cannot be overlooked that many industries have not followed closely either cheap power and raw materials or favorable living conditions; for example, iron and steel mills are not located in Northern Minnesota and many textile mills are not near cotton or wool-producing sections. Markets, labor supply, and transportation facilities are generally given greater weight than the other factors in locating all industries except those producing foodstuffs. As a typical example, the iron and steel industry has been satisfactorily located on the southern shore of Lake Michigan, because at that place iron ore from Duluth, Minn., and cheap coal from Southern Illinois meet at a point adjacent to the markets and an adequate dependable labor supply.

It would not be possible, of course, to expand all the industries listed in Table 4 within a short period of time. New ones could be developed concurrently with the irrigated lands that will be made available by the Central Valley Project. These lands will form an agricultural base which will be capable of supporting a rapid population growth and, if industrial expansion is correlated with agricultural growth, the population density will increase at even a greater rate.

CORRELATION OF INDUSTRY AND AGRICULTURE

For example, assume that much of the industrial deficiency shown by Table 4 will be made up in the period between 1935 and 1945 through a co-ordinated industrial and agricultural development. Fig. 1(*b*) indicates that the increase in the area of irrigated lands of the State during that period will be about 800 000 acres and Fig. 1(*a*) that the population increase for the State will be about 2 000 000.

It is reasonable to assume that between 1935 and 1945 200 000 industrial employees, in addition to those employed in California in 1929, can be settled permanently in rural districts and can divide their working time between agriculture and industry. If 1 acre of land were allotted to each employee for gardening purposes, only one-fourth the increase in the area of irrigated land would be devoted to co-ordinated agricultural and manufacturing operations.

To provide for the continued future development of irrigated lands, as indicated by Fig. 1(*b*), more water will be required than that which will be furnished by the present Central Valley construction program. These additional supplies will be secured from other reservoirs contemplated in the State's comprehensive plan of water development.

The foregoing examples indicate broadly the opportunities for industrial expansion that exist within the State and also show that future industrial growth could be absorbed by the Central Valley without changing materially the program of agricultural development now planned for California. Although this exposition demonstrates the relation of the entire Central Valley to potential industrial development, it does not show in detail the economic benefits that could be obtained by co-ordinating agriculture and industry. A more comprehensive picture of the possibilities of decentralized industrial planning is needed, and this may best be obtained by a detailed study of a specific project.

PART III.—POSSIBILITIES OF MADERA IRRIGATION DISTRICT AS LOCATION FOR CO-ORDINATED INDUSTRIAL AND AGRICULTURAL PROJECTS

GENERAL DESCRIPTION

The Madera Irrigation District in California is suitable for combined industrial and agricultural development owing to its proximity to important markets, its climate, its large undeveloped areas of fertile soils, and its available labor supply. Fig. 2 shows its relative location. This District is situated in the heart of the San Joaquin Valley, about 150 miles southeast of San Francisco, 150 miles southwest of Stockton, and 22 miles northwest of Fresno, the latter being the largest city in the San Joaquin Valley. The San Joaquin River comprises the southern boundary of the District and the Chowchilla River, the northern boundary. The San Joaquin River has an annual run-off of about 1 750 000 acre-ft per yr, most of which comes down in the flood season of May and June. The Chowchilla River is a flood-water stream, with an average run-off of about 50 000 acre-ft per yr. The District is intersected about midway by the Fresno River, which is also a flood-water stream, with an average run-off practically equal to that of the Chowchilla River.

The total area of the District is 173 179 acres, of which 32 719 acres are rough hardpan, of doubtful value for irrigated land under present economic conditions, and 13 872 acres are irrigable, but not as satisfactory for cultivation as the better class of land. The remainder of the District, or 126 588 acres, is first-class, flat, irrigable land, of which 75 000 acres are now irrigated and cultivated and 51 588 acres are not irrigated. The latter area, which is now (1936) partly used for raising grain, is available for either industrial co-operative gardening or for independent agricultural development. For the purpose of this investigation, it has been assumed that about one-half the first-class available land, or 25 000 acres, will be taken up by combined industrial and agricultural developments.

Population and Labor Supply

The Madera Irrigation District includes two cities within its limits, namely, Madera, with a population of about 6 000, and Chowchilla, with a population of 1 000. The rural population is estimated to be about 7 000, making a total population for the District of 14 000. Aside from these permanent residents, there is a large transient laboring element which follows the cotton and fruit seasons.

Most of the labor available is unskilled. If permanent employment were offered, a large portion of the transient labor would settle permanently in the District and skilled labor would also be attracted. A number of workers are available in winter when they are not engaged in agriculture, and many men who work in the granite quarry and logging camps have extensive "off" seasons. As living conditions within the District are excellent, no difficulties would be experienced in attracting an ample supply of both skilled and unskilled labor.

Climate and Rainfall

The average daily maximum temperature for the year is 75 degrees. The temperature varies from a minimum of 36° in January to a maximum of 99° in July. The climate is dry and exceptionally healthful. Regardless of the high maximum temperatures that are attained during the summer, personal discomfort is seldom experienced owing to the low humidity.

The average annual rainfall is 9.56 in., which is typical for the arid lands of the San Joaquin Valley requiring irrigation. About 85% of the seasonal rainfall comes in the six months between November and April, with a yearly average of about 45 days of rain. There is a peculiar tendency, especially in the spring and autumn, for the rain to occur at night; so there is little interference with work. The climatic conditions of the San Joaquin Valley are especially favorable to industrial development.

Water Requirements and Water Supply

For the purposes of this investigation an analysis has been prepared on the premise that the District was fully developed in 1929. In the following analysis, it has been assumed that 25 000 acres of the first-class land has been utilized by industry for co-operative gardening purposes and that the remainder is developed by individual farmers.

Probably not more than 85% of the available land, or 119 000 acres, will be irrigated in any single year. The remaining 15% may be dry farmed, temporarily, or allowed to lie fallow. The quantity of water that will be required by the project, therefore, will depend upon the relative acreages of the respective crops that are grown upon this land. Table 5 shows the land use assumed in making this investigation and also the water requirements for each crop.

TABLE 5.—Land Use Assumed in Investigation

Crop	Area, in acres	Duty, in acre-feet per acre	Total consumption, in acre-feet
Alfalfa	28 200*	3.0	84 600
Cotton	18 800*	2.5	47 000
Trees and vines	23 500*	2.0	47 000
Grain	9 400*	1.5	14 100
Miscellaneous field crops	9 400*	3.0	28 200
Truck	4 700*	3.0	14 100
Industrial gardens	25 000	3.0	75 000
Total for irrigation	119 000	2.6	310 000
Domestic and industrial use based on future population of 150 000	....	....	17 000
Total annual consumption	....	....	327 000

* Based on percentages used in forecasting demands for Central Valley Project.

A large part of this required supply may be drawn from the San Joaquin and Fresno Rivers after the Central Valley Projects have been constructed. Experience in this District has shown that 25% of the gravity water diverted from the San Joaquin River will be lost by lateral seepage and of this quantity 15% will be recovered by pumping, the other 10% being completely lost. The quantity of water, in acre-feet, to be taken from each source of supply, therefore, is estimated as follows:

From Fresno River	20 000
From San Joaquin River, 258 000 acre-ft, of which three-fourths reaches the land	193 000
Pumped from natural underground recharge	75 000
Pumped from artificial recharge, 15% of 258 000 acre-ft	39 000
Total delivered to land and industries	327 000

This quantity is only about 10% in excess of that which would be required if the District were developed as an agricultural project alone.

Cost of Water Supply

It has been estimated that the cost of water from the San Joaquin and Fresno Rivers will be $3.00 per acre-ft after the construction of the Central

Valley Projects. The average cost of pumping in the Madera District is $0.05 per acre-ft for each foot of lift. For the average lift of 65 ft which exists at present, the average total cost of pumping is $3.25 per acre-ft. This value will apply only after the Central Valley projects are constructed. As the groundwater is now (1936) lowering rapidly, pumping charges will be increased if new sources of supply are not obtained. On the basis of the foregoing unit costs, the total cost of water may be estimated as follows:

Gravity supply, 278 000 acre-ft @ $3.00......	=	$834 000
Pumped supply, 114 000 acre-ft @ 3.25......	=	370 000
Operation and maintenance of gravity system	=	120 000
Total cost of water per year............	=	$1 324 000

$\frac{\$1\,324\,000}{327\,000\text{ acre-ft}}$ = $4.05 per acre-ft, or only 1¼ cents per 1 000 gal, at the land or factory

The proportion of the total annual cost required for each use would be:

Industrial gardens,	75 000 acre-ft @ $4.05	=	$303 750
Industrial and domestic use,	17 000 acre-ft @ 4.05	=	68 500
Independent agricultural development,	235 000 acre-ft @ 4.05	=	951 750
Total	327 000 acre-ft	=	$1 324 000

The construction of the Central Valley Projects will make available an adequate and low-cost supply of water for both agricultural and industrial purposes.

POWER

An ample quantity of power is available for both industrial and agricultural needs. Power charges vary from a minimum of 55 cents per kw-hr for a monthly consumption of more than 5 000 kw-hr, to a maximum of 4.0 cents per kw-hr for general power service.

SOILS

The soils of the Madera District consist principally of sandy loams of excellent fertility, suitable for raising alfalfa, grains, trees and vines, truck, and other field crops.

LAND OWNERSHIP AND VALUE

All the land in the District is privately owned although a large part of it is in the hands of banks and mortgage companies. This situation, which is not uncommon to irrigation districts, as well as other farming areas, points to the need for a re-adjustment in irrigation planning. Obviously, a greater population density is needed, and this may be obtained most readily by industrial developments related to the land as a population base.

Holdings in the District range in size from about 20 acres to 320 acres, with an average of about 80 acres. Values of agricultural land depend at present upon the relative fertility of the soil and the comparative ease with which underground water may be developed. Grain lands, considered non-irrigable under present conditions, are worth from $18 to $25 per acre. Land adapted to the growing of cotton, vines, deciduous fruit, etc., is valued at from $75 to $125 per acre.

TRANSPORTATION

The Madera District is traversed by the Southern Pacific and the Atchison, Topeka, and Santa Fé Railroads which connect it with the most important market areas. Many of the products of the District are transported by truck to Fresno where they are taken over by jobbers and packers for refrigeration and shipment. The average length of haul to Fresno is about 25 miles, and the hauling rates vary from 8 to 12 cents per ton-mile.

VALUE OF CROPS

An estimate of the annual gross value of the crops, if the District were completely developed, is given in Table 6. The prices upon which this estimate is based are the average f.o.b. values per acre for the seasons of 1929 to 1934, inclusive.

TABLE 6.—VALUE OF CROPS

Crop	Area, in acres	Value per acre	Total gross value
Industrial gardens	25 000	$100,00	$2 500 000
Alfalfa	28 200	66,00	1 870 000
Cotton	18 800	55,00	1 040 000
Trees and vines	23 500	94,00*	2 210 000
Grain	9 400	19,00	180 000
Miscellaneous field crops	9 400	50,00	470 000
Truck	4 700	100,00	470 000
Total	119 000	$73.44	$8 740 000

* Based on average value for San Joaquin Valley; derived from data given in "Permissible Economic Rate of Irrigation Development."

The average gross value of crops per acre of crops for the years 1929 to 1934 is about two-thirds of the value for 1929[13]. On this basis the average gross value per acre for the Madera District in 1929 would have beeen $110 per acre, and the total gross value of crops for the District would have been $13 090 000.

The gross value per acre of crops for the Madera District, on the 1929 basis, compared favorably with those of the most productive Federal Reclamation Projects, as follows:

Project	Gross average value of crops per acre (1929 basis)[14]
Okanogan, Washington	$250
Yakima, Washington	120
Madera, California (estimated)	110
Yuma, Arizona	90
Carlsbad, New Mexico	75

---

[13] Rept. on Federal Reclamation, by J. W. Haw and F. E. Schmitt, M. Am. Soc. C. E., p. 63.

[14] *Loc. cit.*, pp. 34 to 58, inclusive.

EXISTING INDUSTRIAL PLANTS

There are seven cotton gins scattered throughout the Madera District from Chowchilla to a region eight miles south of Madera. There is also a cottonseed mill and a creamery at Chowchilla. There are three wineries within the project, with a combined tankage of 2 757 000 gal, and also a lumber mill with a capacity of 5 000 000 fbm per season.

FUTURE INDUSTRIAL DEVELOPMENT

It is impossible, of course, to forecast accurately the kinds of industries that may be attracted by a given situation. All that may be accomplished in this investigation is to demonstrate the possibilities of co-ordinating industry and agriculture within the District by studying the characteristics of the area and of a selected group of manufacturing plants. Table 7 gives a list of industries that could be located within the Madera District and also certain average relationships which have beeen computed from the statistics for these industries in the Industrial Census of 1929.

TABLE 7.—INDUSTRIES THAT COULD BE CO-ORDINATED WITH AGRICULTURE ON MADERA IRRIGATION DISTRICT

Industries	Persons in industry	Number of establishments	Salaries	Wages	Cost of materials	Value of products	Value added by manufacture
(*a*) INDUSTRIES ENGAGED IN PROCESSING AGRICULTURAL PRODUCTS							
Leather, tanned, curried and finished..........	2 000	17	$576 000	$2 340 000	$12 400 000	$17 700 000	$5 300 000
Boots and shoes........	5 000	30	1 000 000	4 950 000	11 400 000	21 400 000	10 000 000
Pocketbooks, purses, and card cases...........	500	11	193 000	635 000	1 470 000	2 840 000	1 370 000
Cotton goods..........	5 000	15	470 000	3 720 000	10 400 000	17 400 000	7 000 000
Woolen goods..........	1 000	7	222 000	1 060 000	2 650 000	4 650 000	2 000 000
Knit goods............	3 200	27	615 000	3 060 000	6 500 000	12 900 000	6 400 000
Wood, turned and shaped, other wooden goods...	500	20	130 000	425 000	660 000	1 620 000	960 000
Sub-Total.........	17 200	127	$3 206 000	$16 190 000	$45 480 000	$78 510 000	$33 030 000
(*b*) INDUSTRIES ENGAGED IN MANUFACTURING MECHANICAL AND ELECTRICAL EQUIPMENT							
Agricultural implements.	800	5	$225 000	$990 000	$1 910 000	$4 600 000	$2 690 000
Electrical machinery....	5 000	22	2 110 000	5 650 000	12 000 000	28 500 000	16 500 000
Refrigerators, mechanical	1 000	2	362 000	1 510 000	3 740 000	8 350 000	4 610 000
Hardware manufacturing	1 000	8	328 000	1 120 000	1 270 000	3 810 000	2 540 000
Sub-Total.........	7 800	37	$3 025 000	$9 270 000	$18 920 000	$45 260 000	$26 340 000
Totals............	25 000	164	$6 231 000	$25 460 000	$64 400 000	$123 770 000	$59 370 000

In listing this group, it was assumed that about one-eighth the total industrial deficiency for the State (see Table 4) would be developed within the Madera District. To have concentrated more industries in this area (on the 1929 basis) would have defeated the purposes of an industrial decentralization program. The plants were selected, therefore, with a view to obtaining a well diversified group producing a total annual value of product equal in amount to about $124 000 000.

The selection of the industries shown by Table 7 was based on the following principles:

(1) Industries were selected that would not compete with existing industries within the Madera District.

(2) The location factors, outlined previously under the heading "Possibilities of the Madera Irrigation District as a Location for Co-Ordinate Industrial and Agricultural Projects", are favorable to each of these industries.

(3) All manufacturing plants listed in Table 7 could have their operations co-ordinated readily with agricultural work, that is, workers could divide their time between the shop and their gardens without interfering with industrial operations.

(4) Two groups of industries were selected: The first relates to the processing of agricultural products, and the second consists of certain industries using mass-production methods in their manufacturing processes. Both groups are compatible with a program of decentralization. Industries engaged in the processing of agricultural products that could be raised within the District would effect large savings in transportation costs and offer ready markets for the raw materials produced by adjacent farms. Workers engaged in mass-production operations, as previously emphasized in this paper, need greatly both the physical diversification and the "back-log" of employment that may be obtained through part-time gardening.

(5) The annual value of the products of each of these plants is either equal to or less than the deficiency of this industry within California in 1929.

(6) Raw materials for each industry may either be produced within the District or brought in by rail or water transportation from adjacent sources of supply.

Approximately 25 000 industrial workers would be required to operate the plants shown by Table 7. As each of these would represent a family of about four, it is reasonable to assume that the total increase in population due to this industrial development would be 100 000. Allowing 1 acre of land per worker for gardening purposes, a total of 25 000 acres would be required for decentralized industrial developments as assumed previously herein.

Markets and Competition

The existing plants in California, manufacturing the products listed in Table 7, would offer little competition to similar industries located in the vicinity of Madera. This fact is shown clearly by Table 8 which gives an analysis of the existing market served by each industry shown in Table 7.

The three industrial areas analyzed in Table 8 are outlined in Fig. 2. Values of products and the population served for each industry were segregated for these three Districts. It will be observed from Table 8 that the population served by most of the industries within each District is now appreciably less than the population of the District. This means that the existing industries are not even meeting the needs of their adjacent areas and, therefore, would not offer much competition outside these areas.

Consider, for example, the products of the plants manufacturing boots and shoes. In the Los Angeles industrial area, the shoe factories served only 203 000 persons, leaving a market of more than 2 000 000 persons in this area who must purchase shoes that are manufactured elsewhere. Table 8 shows that the plants manufacturing agricultural implements serve more persons than the population listed under "Remainder of State." A deficiency for this product however, exists within the State, and this justifies the inclusion of such plants in Table 7.

ECONOMIC BENEFITS RESULTING FROM CO-ORDINATED AGRICULTURAL AND INDUSTRIAL DEVELOPMENTS

The best way to visualize the financial improvement that would result from developing within the District the industries shown by Table 7 is through comparative statements showing the possible results of operating the District, first as an agricultural project alone, and then as a combined industrial and agricultural project. In preparing such statements, the gross annual value of the crops may be compared with the total value of the products given by Table 7. The gross values of the crops represent the prices at the land, before transportation and other charges have been added. The values of products likewise represent the prices at the factory. Both these values are measures of benefit to the agricultural and industrial workers as their individual net incomes should vary in proportion to gross values. It would be better, of course, to base the comparison on the net income per capita before and after the introduction of industrial plants. Unfortunately, such an investigation would involve lengthy studies of agricultural and industrial production costs which vary so widely that generalizations would have little or no value.

In Table 9, the District is assumed to be fully developed. It must not be understood from this comparison that industrial workers would have nearly twice the average net income earned by agricultural workers. It would be reasonable to assume that about one-half the gross agricultural income per capita would be represented by production costs leaving a net average income per capita of $260. This would correspond to the average wage per capita of the industrial population which is estimated from Table 7 to be, $\frac{\$31\,691\,000}{100\,000}$, or $317.

TABLE 9.—COMPARATIVE ESTIMATED STATEMENTS OF ECONOMIC CHARACTERISTICS, 1929 BASIS

Description	Agricultural development	Industrial development	Total co-ordinated agricultural and industrial development
Population	25 000	100 000	125 000
Value of product	$13 000 000	$124 000 000	$137 000 000
Value of product per capita	$520	$1 240	$1 100

With the improvement in agricultural prices that will follow recovery, there is every possibility that the incomes of agricultural workers and industrial workers would be about equal. It is certain that the industrial worker would have nothing to lose by devoting part of his time to gardening as the land utilized for raising truck yields a rate of return that would probably exceed industrial wage rates. On the other hand the worker has everything to gain by having an alternate source of employment during lay-offs and slack periods.

As indicated in Table 9 the population with combined industrial and agricultural developments would be at least five times that of the District if it were devoted to irrigation farming alone. This does not include the great number of additional people that would be necessary for professional and commercial occupations. Although this part of the population is difficult to estimate, it is certain that the increase would be substantial. Tables 1 to 9, therefore, do not include all the benefits of decentralization, industrial construction, highways, schools, churches, and buildings, because social institutions would all help to develop the population and would bring tremendous benefits to the District as a whole.

OPERATING PLAN FOR DECENTRALIZED INDUSTRIAL DEVELOPMENT

The assumption that 1 acre would be cultivated by each industrial worker is rather liberal for the needs of the average family and is greatly in excess of the actual requirements for a subsistence basis. The writers, however, advocate an abundant rather than a subsistence level of living. The care of 1 acre of ground would require about 1.5 days per week per worker if the plots were operated according to the centralized plan as developed in Examples 1 and 2. As a matter of fact, industrial gardening on irrigation projects could be operated under no other plan, as it would be impractical to water and care for widely scattered projects.

Experience has shown that clearing and preparing the industrial gardens for planting could best be handled by the several companies within the District. The land adjacent to the plants could then be laid out in plots which would be assigned to the individual workers. The rotation plan of operation is not recommended as this removes the incentive derived from individual accomplishment.

Educational measures and strict supervision are absolutely essential. It would not be necessary for each plant to employ a trained agriculturist as one organization could handle the agricultural operations of several concerns. In addition to direction and education, the supervisor and his assistants would purchase and distribute seeds and also would manage the storage, distribution, and marketing of the agricultural products. Central storage facilities and distribution systems would be provided by each company. This measure is necessary to insure both the proper care and handling of the produce and a minimum of spoilage.

Conclusions

The foregoing detailed study indicates clearly that economic improvement would follow the co-operation of industry and agriculture on irrigated areas. It is not within the scope of a single paper, however, to present a quantitative analysis that even begins to show the potential benefits made possible by the great water conservation projects now (1936) being constructed.

New thinking is necessary if these results are to be achieved. One cannot view the areas affected by Boulder Dam, or by the works now (1936) being constructed in the Central Valley, the Columbia Basin, or the Tennessee Valley, in terms of flood control, power, or irrigation alone. Larger objectives will be attained if the new lands made available by each project are considered as a population base for a potential industrial development. It is entirely possible that many future industrial areas will develop about water conservation works rather than about congested cities.

These new industrial areas will not be limited by either State lines or other political boundaries; markets and transportation costs will determine the competitive limits within which the complementary industrial and agricultural developments of a water conservation project may serve economically. For example, the area which the future industries of the Central Valley project could serve may be much greater than that of the State of California as assumed in this investigation. To determine accurately the total potential industrial growth of the Central Valley, investigations should be made for the purpose of establishing the limits of the competing areas that will be adjacent to the Columbia Basin projects, to Boulder Dam, and to other projects suitable for industrial development. Obviously, such investigations must have an important place in future national planning.

Widespread industrial decentralization correlated with water conservation can be brought about only by the joint efforts of business and the Federal Government. Manufacturers are turning to industrial decentralization principally because it is profitable. The opportunities for profitable industrial expansion will follow the extensive water-shed development programs that have been sponsored by the Government.

Industrial relocation in rural areas and subsequent co-ordination with agriculture will be beneficial to the entire country. The markets for both agricultural and industrial products will be brought closer together; therefore, decentralization will aid materially in the solution of the distribution problem. Existing industrial areas will not be affected adversely by such a movement; as a matter of fact, relief from over-congestion, due to the abandonment of many obsolete plants, accompanied by the migration of both the industry and its employees, would prove a positive benefit to many cities. Modern production units in healthful locations would replace many of the huge antiquated plants that are now found so frequently in industrial centers.

The stabilization of income through occupational diversification would result in a tremendous increase in demand for all products, and lower production costs would put these products within reach of the workers. It is safe to say, therefore, that the plants moving away from industrial cities would eventually create about them their own markets and would not injure or compete with the plants within existing industrial areas.

It is recognized generally that the present demand is not near the saturation point. What average person, for example, would not be glad to double his (or her) wardrobe if economic conditions permitted? A little thought will show that this situation extends into every department of modern life; a tremendous potential demand is thwarted by putting the products of industry just out of the wage earners' reach. Once these obstacles are overcome, it is safe to say that the total industrial production capacity of the nation will be found to be entirely inadequate.

Actual experience has proved that labor is ready and willing to accept both diversification and decentralization. This transition cannot be accomplished over night; considerable training and re-adjustment will be necessary before the benefits of decentralization may be realized. The end results, however, will more than justify the cost.

The diversification of labor would curtail the over-expansion of farm lands by eliminating from competitive use the areas devoted to industrial gardening. These gardens would not take away part of the existing market for agricultural produce; actually, they would help to lift the burden of relief which is not only robbing the farmer of his market, but increasing his tax load as well. The unemployed man cannot buy produce; it must be given to him, and the farmer now helps with the giving. It is safe to say that the greatest losses of the depression have been the production losses due to idle time. Any system that will help to capitalize idle time, will also reduce the relief load, and thereby improve the economic condition of the entire country. Such improvement results inevitably in better markets for the products of both agriculture and industry.

To summarize, water conservation projects correlated with combined manufacturing and farming developments would assist in bringing about the balance between industrial and agricultural production that is necessary to economic stabilization.

ACKNOWLEDGMENT

This paper offers no brief for any formalized system of government, or controversial class philosophy. The suggestions herein contained are as applicable to the present industrial system and democratic form of government as to any other form. The paper has been kept as free from the mention of specific commercial names as possible in order to emphasize the purpose of the various examples as representative of their kind rather than as an effort to promote a certain isolated case.

Because of the importance of their contribution, however, free acknowledgment should be given to: Edward Hyatt, and Harry Barnes, Members, Am. Soc. C. E.; T. G. Graham, Vice-President of the B. F. Goodrich Company, of Akron, Ohio; A. E. Peters, General Superintendent of the Ingersoll-Rand Company, of Phillipsburg, N. J.; F. O. Hagie, Managing Secretary, Chamber of Commerce, Yakima, Wash.; Mr. F. Stewart Fitzpatrick, Manager, Construction and Civic Development Department, Chamber of Commerce, Washington, D. C.; Mr. Charles F. De Bardeleben, President, Alabama Fuel and Iron Company; Mr. John W. Haw, Director, Agricultural Development Department, Northern Pacific Railway Company, St. Paul, Minn.; Miss Mae A. Schnurr, Assistant to the Commissioner, U. S. Bureau of Reclamation, Washington, D. C.; Mr. John P. Ferris, Tennessee Valley Authority, Norris, Tenn.; C. D. Adams, General Superintendent, Holly Sugar Corporation, Sidney, Mont.; and J. J. Haly, Jr., Administrative Assistant, Department of Public Works, State of California, Sacramento, Calif. Fig. 1 of the paper was prepared from data supplied by research at the University of California. Unpublished data from the private files of the foregoing organizations, in large measure, form the basis for the paper.

DISCUSSION

JOSEPH JACOBS,[15] M. AM. SOC. C. E. (by letter).—One reads with admiration and, in the main, with approval, the forceful presentation made by the authors, of a phase of economics and sociology not often approached from the engineering angle. It is, in other words, the application of engineering analysis to certain economic and sociological problems which all too frequently in the past have measurably lacked that desirable form of analysis. It deals specifically with a phase of national development that is likely to become, if it is not already, an active political issue. The West understands and appreciates the benefits of reclamation, believes it to be a national asset of great importance, and if its value can be materially enhanced in the manner indicated by the authors, it is a matter of national economy and of national well-being in which every one has a vital stake—a consummation to be desired and to be striven for.

Some, no doubt, will feel that the authors are perhaps too optimistic as to the extent that major industries may advantageously be decentralized and transplanted to newly developed, or long existent, reclamation areas, and that the doctrine of self-sufficiency may be over-emphasized. That there are, however, distinct possibilities in that direction, and that there are some present tendencies toward industrial decentralization, there can be no question. Without intent to take issue with any of the authors' contentions, the writer desires to submit a few brief comments on their main thesis, as follows:

(*a*) A well balanced distribution of industry and agriculture is desirable and, unquestionably, diversification of occupation and decentralization of industry afford social advantages as pointed out by the authors. However, with the nation's splendid and steadily improving transportation and communication systems, complete balance for individual areas is not absolutely necessary and, in many cases no doubt, not entirely desirable or possible from economic considerations. In general, both industrial and agricultural production should be fostered and expanded only in those localities which are best adapted to the particular industry and the particular agriculture in question. Development should not be unduly forced on a fetich of self-containment.

(*b*) If California is not entirely self-sustaining as to some industries; that is, if it is not a completely balanced economic unit, it is more than self-sustaining as to other industries for which it has a nation-wide and, to some extent, a world-wide market. Certainly, it would not desire to surrender these markets. Other States and other localities are similarly situated and that is, by no means necessarily, an unwholesome situation.

(*c*) More can be said for the need of national self-sufficiency than for State or local self-sufficiency. However, with a broadening of understandings and of amicable agreements between nations, and again with the steadily improving transportation and communication systems in the United States, even complete national self-sufficiency, in the aforementioned sense, is far from being a present-day imperative necessity. An active interchange of world trade is highly important to national prosperity and, similarly, an active interstate commerce is of high economic value. These desirable ends would be largely sacrificed if the doctrine of self-sufficiency is carried too far in practice.

---

[15] Cons. Engr., Seattle, Wash.

(*d*) Important developments in the direction indicated by the authors are no doubt possible and desirable, but there is always economic danger in broad generalizations, and caution is essential in the application of new economic theories and doctrines. The fact is that each particular industry, and each particular locality, demands a detailed economic analysis by experts in the particular lines involved before a safe program in respect thereto can be outlined. That the authors recognize the essential correctness of this statement is evidenced in their discussion of "Location Factors."

It is noted (see heading "Cost of Water Supply"), that a uniform price of $4.05 per acre-ft is designated for all classes of water use. If the water charge for industrial and domestic use were increased three or fourfold (a charge that could readily be borne for those uses), it would permit a material decrease in the charge for irrigation water. Industrial gardens can stand a heavier water charge than general agriculture but, for either, a charge of $4.05 per acre-ft, which amounts to from $10.00 to $12.00 per acre per season, is rather heavy—much heavier than is customary on most irrigation projects. A variation of rates for the different uses would seem to be desirable.

M. E. McIver[16] (by letter).—It is re-assuring to find engineers supporting remedial measures, such as those suggested in this paper. The writer believes that the future may be considered safe when engineers, rather than sociological and political theorists, prescribe for the ills of society.

The paper contains the kind of "medicine" for social and economic ills that the late Henry Arnstein, noted Consulting Chemist of Philadelphia, Pa., urged in the pages of every publication available to him. "Get the most out of natural resources", he pleaded, and his doctrine was more widely accepted in the thirty foreign countries to which he was special adviser in conservation policies, than in his own wealthy and profligate country.

The authors should add to their treatise an appeal for the development in the areas described, not only of branches of old established industries, but of new manufacturing agencies to produce—from surpluses, and from waste material—synthetics suitable as substitutes for material now imported. That was the final treatment in Dr. Arnstein's formula for changing a wasteful nation into an independent and stable power.

Much of the appalling extravagance of the last few years will be compensated and the future tax burden not only justified but "written off", if the policies outlined in this paper can be put into practice; and great social values can thus be developed from mere (but inconceivably expensive) power projects. Engineers should teach the politicians to go on to the ultimate Arnstein project and demand that, in addition to reforestation, for example, they learn all the synthetic possibilities of every splinter of every tree that is cut; that instead of merely making more sugar to compete with "reciprocity" sugar, the new industries be encouraged to develop fuel alcohol; and, that in some of these areas, the dyestuffs and fertilizers and hundreds of other products now imported, may be produced by engineering research magic from surplus and waste. Engineers will have occasion for greater pride in their leadership in the field of conservation than in the construction of the tallest buildings or the biggest bridges, which seem to be the largest scale production now attributable to engineering knowledge and skill. The latter utilities are evidence of genius, but conservation progress is genius plus patriotism.

[16] Secretary, Am. Assoc. of Engrs., Chicago, Ill.

C. S. JARVIS,[17] M. AM. SOC. C. E. (by letter).—The clearly expressed views presented in this paper are both impressive and convincing because of the sound logic used, the practical examples cited, and the reasonable conclusions reached. Such examples and principles must be relied upon largely for future guidance in the decentralization of industry, orderly diversification of labor, and co-ordination of agriculture with other essential and basic industries.

Pioneers and frontiersmen generally have had to develop ingenuity in shifting for themselves, to become both self-reliant and reasonably self-sustaining, and thus to become largely immune to the hardships ordinarily attending isolation. Over-specialization of industry in crowded centers has had the opposite trend and effect; any reasonable means for bringing about decentralization of industry and diversification of labor, especially among rural surroundings and in more or less closely related branches of agriculture, should be encouraged.

Too often such motives have been announced, the colonies and industries established, the land subdivided and disposed of at rising prices, only to suffer collapse when it has been demonstrated that the proposed industries cannot thrive under local conditions as to raw materials, power, labor, water supply, or market. In other instances, smelters and mills for the reduction of ore have been established in rural communities, only to be shut down and removed after conclusive demonstration that the by-products of flues and the odors or dust attending the processes, and the effluents from drains are objectionable and harmful to various forms of life. Many communities have been brought to the realization that they have paid too high a price for industrial activity and temporary prosperity, when they discovered the deleterious effects of pollution in atmosphere, streams, pastures, fields, orchards, and in the soil itself. Other objectionable effects have attended the establishment of industries with characteristically unpleasant and noxious odors.

If the well-matured studies and procedure associated with community planning are utilized in connection with both reclamation and the various industries that are considered in an effort to promote a stabilized industrial activity, there is reason to expect attainment of the desired objectives, with avoidance of the costly errors so often experienced heretofore. Long-range planning implies the consideration of all lines of activity and growth that may be reasonably foreseen or imagined, with adequate provision for each essential element of the industrial system along with agriculture and its ramifications, and finally, adjustment and reconciliation of their divergent requirements.

---

[17] Cons. and Hydr. Engr., SCS, Washington, D. C.

The citizens of the country must recognize and adjust themselves to the inevitable trend away from the smallest industrial units—the "single run-of-stone" grist-mill, now generally supplanted by roller mills; the water-driven, seasonally operated saw-mills and planing mills or wood-turning shops, ordinarily giving way to electrically operated all-year plants; the small textile factories unable to compete with the larger units or associations, and, therefore, readily absorbed during dull periods at bargain prices; the small tanneries, cement works, lime-kilns, foundries, glass works, canneries, dehydration plants for fruit and vegetables; the small creamery, ice-plant, storage warehouse, laundry, and indeed nearly all the ordinary commercial and manufacturing enterprises. The increasing complexities of accounting, inspection, chemical analysis and testing, research laboratories, water supply, fire protection, storage, buying of raw materials at favorable prices, marketing of the finished product, smoke abatement, industrial and household waste disposal, and maintaining good-will of customers and of public officials—all these have seemingly grown beyond the capacity of an individual or of a small group. They demand a technical staff with background and experience as broad as the problems they will be likely to encounter. The dependence of a highly trained staff, the operators, and their families, upon the stability of the enterprise calls for the maintenance of a substantial reserve of both raw materials and finished products, as well as substantial credit and liquid assets, to bridge over periods of depression.

For those occasional instances where a small industry can thrive, such as for corn-meal or other feed-grinding units at a centrally located farm, convenient to dependable and low-cost power, there should be an attractive future as long as the quality of the product is conscientiously maintained according to acceptable standards. Service to certain farms with heavy tonnages may be rendered to best advantage by means of portable grinding units. As such work is usually seasonal in character, and follows the main harvests of grain, it could well be one of the auxiliary activities maintained in connection with a well-equipped farm.

Other services, trades, and specialized work are normally in demand wherever a community establishes itself and has a reasonable assurance of continued growth and prosperity; but none of them has so nearly a guaranteed supply of raw materials nor so wide a market demand as have those branches of agriculture which furnish foodstuffs within ready access of population centers. The important part of the unemployed families' living supplied by the industrial co-operative garden projects, as described so interestingly by the authors, vividly illustrates the nearly independent status of rural home owners with small acreages and skill, industrious habits, and enthusiasm for agricultural enterprises appropriate to the region. To such a citizen, trained to thrifty ways and inclined to make some provision for the future, occasional interruptions of industrial employment mean merely a better opportunity to concentrate on his gardening or such other activities as he has established, more rigorous reduction of expenditures, depletion of savings, or a combination of such measures. He is not facing unemployment, but rather the problem of adaptation to available employment.

It must be recognized that many individuals and families are quite unfitted by natural inclination, training, and habits of life to become contented and dependable members of rural communities relying mainly upon agricultural pursuits. Early Colonial history and subsequent frontier life in this country afford many examples of failure because of unwillingness or inability to forego the use of seed-grain and vegetables during periods of privation, when such temporary appeasement of hunger plainly meant another season of famine or abandonment of the venture, admitting defeat at their own hands and under the stress of circumstances.

Granting that improved means of communication and the recognition of society's responsibility to aid individual members during emergencies have radically changed the outlook for struggling colonists and "back-to-the-soil" devotees, some vestige of that self-restraint, control over appetites, and long-range planning for economic stability must be maintained if resettlement projects are to prosper in an approach to their main objectives. Among these are decentralization of industry, diversification of labor, co-ordination of agriculture with other basic industries, thereby establishing a positive defense against the recurrent depressions, temporary collapse of property and security values, disorganization, distress, discouragement, and attendant ills.

On many reclamation projects where irrigation is the main dependence for crop production, snow surveys afford a satisfactory index to the season's water supply. If reservoirs provide considerable carry-over from years of surplus, the inclination is to draw a minor portion of such reserve during any one season. During years of extreme drought, and before adequate reservoirs are provided, it occasionally happens that the limited irrigation supply is required mainly within orchard and small garden tracts. The main recourse for the growing of forage and grain crops, under such circumstances, has been dry-farming, resulting in the improvement of methods and the pronounced extension of areas within which it has proved moderately successful, year after year. Even such persistent weeds as the Russian thistle provide excellent, succulent pasturage as long as they are kept closely grazed; and the mature plants have much nutriment available for livestock if included with ensilage, or if moistened thoroughly to soften the thorny spikes.

Unfortunately, mounting tax rates have become more and more burdensome to the land-holder and home owner, and this item is not subject to curtailment during periods of depression and retrenchment. If the assessed valuation of a county is reduced, the requirements for revenue result in a proportionate increase of tax levies, thus leading to delinquencies and ultimate forfeiture unless normal market demands and prices for agricultural products are restored without undue delay.

Either depression or prosperity incident to agriculture seems to be reflected throughout the national economic structure sufficiently to make the co-ordination and stabilization of its various branches, along with other basic industries, one of the foremost national problems of to-day.

JOHN P. FERRIS,[18] ESQ. (by letter).—This paper states the case for an attempt to create a new industrial region to accompany a new agricultural region, which latter would normally be expected to come into existence as a result of a major reclamation development.

The National Industrial Conference Board reports[19] a startling displacement of employment in agriculture relative to other types of employment. In 1930, about 88 persons per thousand of the population of the United States were employed in agriculture, whereas two generations earlier (1870) there were about 180 persons per thousand thus employed. A variety of causes accounts for this astonishing shift, some of which the writer has discussed elsewhere.[20] As this displacement has occurred in existing agricultural regions it is natural that it has produced a large surplus rural population. In many counties in the rural Southeast this surplus appears to be from 400 to 1 800 workers.

The nation, therefore, faces a parallel problem to that discussed by the authors—the problem of the region that is being subjected to excessive drainage of both human and material resources. In such areas the outgo exceeds income, and the "books" are balanced by a continual depletion of basic resources and by increasing debt.

Migration is beset by great practical difficulties. A logical starting point for the diffusion of industrial employment into rural areas seems to be in some of the regions of increasing surplus rural population, where, at the same time, the new "framework" of roads and power can be made available. Of course, a number of the new water-shed projects are situated in such areas.

Surplus rural population results both from the large technological displacement in agriculture generally, and from the high birth rate in many rural areas; for instance, the farm population of the South, in the opinion of O. E. Baker,[21] Senior Agricultural Economist, Bureau of Agricultural Economics, U. S. Department of Agriculture, is multiplying at a rate which may result in its contributing approximately ten times as many people to the national total at the end of a century as an equal number of adults in the large cities.

In connection with this matter of population, the data of the California Water Project Authority seem to be open to question. Messrs. Warren S.

[19] "Gainful Workers per 1000 Population in the United States, 1870–1930", *Bulletin*, National Industrial Conference Board, Inc., August, 1932, Chart No. 283, Road Maps of Industry Series.

[20] "Industry, Agriculture, and Population Readjustment", *Mechanical Engineering*, 1936.

[21] Opinion expressed in 1936 in a letter to the writer.

Thompson and P. K. Whelpton, of the Scripps Foundation for Research in Population Problems,[22] estimate that in 1960 the population of California will be about 7 940 000, instead of 11 600 000 estimated by the Water Project Authority.

The writer is in hearty agreement with the authors concerning the desirability of diversification of employment. Many of the benefits, however, are achieved provided there is diversification within a small area; it is not necessarily most efficient for an individual to work both on the farm and in industry. Much can be said for an arrangement under which some member of a farm family spends his full time in farming, with industry and related rural community services absorbing the surplus workers from farms. This preserves the family farm system, which has many advantages, both in the matter of incentives and in the matter of security. Although many of the part-time farming or gardening projects to which Messrs. Goodrich and Davis refer, have been measurably successful, the fact that the land is worked by non-owners with no permanent security has caused many of these enterprises to be regarded by the participants as emergency relief, rather than as a way of living.

A third form of decentralization which has occurred in many parts of the country, results from highly developed transportation facilities and widespread availability of electric power in hundreds of the smaller towns. An increasing number of city workers with cash incomes are actually living on farms near industrial centers and "commuting" back and forth, the cost being divided among the several workers who ride in each car. Such families are supplementing their income from industry with some "live-at-home" income derived from small tracts of their own land.

Such programs as the foregoing, as well as the type of development proposed by Messrs. Goodrich and Davis, assume a new relation of industrial location to the national welfare. In the first stages of America's economic development, the basic soil economies shaped manufacturing developments. McCormick manufactured his reaper at Chicago, Ill., because this city was a commercial outpost in communication with the great wheat area, and because coal and steel could be shipped cheaply from Pennsylvania on the Great Lakes waterway, and, later, on the east-west railroads. Settlement of the industrially skilled immigrant populations from Europe naturally followed these same transportation routes.

Now, however, the country seems to be entering a new stage, one in which industry can exert a powerful guiding force in shaping the basic economies under which the people live. To-day, there are "network" systems of roads and electric power; many industries no longer find it necessary, as they did in the past, to huddle in large cities along the few old transportation "arteries." Industry can, to a much greater extent than ever before, now establish the location of its demand for the materials which it buys and thus influence the location of their production.

---

[22] "Estimates of Future Population by States, 1935 to 1960", Oxford, Ohio.

L. C. Gray,[23] Esq. (by letter).—According to the authors, advantages would accrue if industry were decentralized and small plants co-ordinated with agriculture in irrigated areas. Under this plan industrial workers in small factories would cultivate small tracts of land, either co-operatively or individually, and would produce at least part of their vegetable food requirements. Undoubtedly, certain advantages can be gained by proper co-ordination of agriculture and industry. However, the number and extent of benefits to be derived appear to be somewhat over-emphasized in this paper.

Both social and economic factors should receive consideration in judging the desirability of such a program. Social aspects are less tangible and less subject to measurement than economic factors, and the relative weight that should be given to them cannot be determined with precision. The value placed on certain social aspects by different individuals varies considerably. What one would consider highly desirable, another might consider undesirable. Because of this fact, the social advantages and disadvantages of decentralizing industry and integrating it with agriculture, have been omitted from this discussion.

The degree of economic success that can be attained by such integration will depend largely upon certain factors influencing the industrial enterprises and agricultural production. Sufficient quantities of raw products should be available under conditions which would allow successful competition with other manufacturers of similar products. In some of the irrigation projects of the West, a large amount of hydro-electric power is available at low rates. Such areas often offer an advantage to manufacturing industries which require large quantities of power, and in which the cost of power represents a large part of the total production cost. Under such conditions the manufacturing of non-agricultural products may assume considerable proportions. A local product can seldom, however, be expected to displace all similar products in near-by markets. If plants have a capacity greater than can be disposed of satisfactorily near-by, competition with more distant plants in other areas at higher transportation costs should be expected.

Conditions should also be favorable to agriculture in the area, both for the production of any raw materials for manufacture and for garden crops. The cost of water in relation to crop values should be moderate. Soil should be fertile and of suitable texture for irrigation. Topography should be fairly level, and other agricultural and water factors should be favorable.

If agriculture and industry are to be co-ordinated according to some such plan on newly constructed projects, the development of the irrigation projects and industrial plants should take place simultaneously. Workers will depend upon industry for the major part of their income from the time they arrive on the project, and farmers will depend on it for marketing their crops. This situation may be difficult to bring about. Irrigation projects usually require heavy expenditures and large units become available for use at one time. If the facilities, both land and power, are not used immediately, losses result. Close co-ordination of the building of the project, the location and building of industry, and colonization is highly important.

---

[23] Asst. Administrator, Resettlement Administration, U. S. Dept. of Agriculture, Washington, D. C.

The extent of integration, and the balance between agriculture and industry which is most desirable, will vary between areas. In some areas large supplies of raw products, power, and adjacent markets may make a high degree of co-ordination desirable, whereas in other areas conditions are such that little if any integration is practicable. A policy concerning the integration of agriculture and industry in irrigation areas, therefore, should be very general in nature. Whether such a plan is applicable to an individual area, and the degree of integration which is most desirable, should be determined for each proposed area after a consideration of the particular circumstances.

It is particularly to the disadvantage of Western agriculture to stress area self-sufficiency since a large part of the production of several of its most important crops depends primarily upon wide distribution. Some past attempts at area self-sufficiency made elsewhere in the United States have worked to the direct disadvantage of certain types of Western agriculture. Rather than to aim at the highest possible degree of area self-sufficiency, as the authors recommend, efforts should be concentrated upon making agricultural and manufactured products which can be produced to greatest comparative advantages in the area. For instance, parts of California have a decided advantage over most of the United States in producing oranges, but have a distinct climatic disadvantage in manufacturing cotton goods. For certain types of metal goods, any marketing advantage may be entirely outweighed by a freight disadvantage in obtaining heavy raw materials.

The authors stress the production of garden products for home use by industrial workers. In addition, some part-time farming could probably be developed to co-ordinate with industry. In present irrigation projects some farmers find periodic work in industries processing agricultural products. Some co-operative plants hire mostly farmers. Successful part-time farming depends upon considerable income from sources outside the farm. Outside work should be available at times not seriously conflicting with important farm work. In addition to farmers finding work in industry through close co-ordination, industrial workers might be used on farms during periods of peak employment, such as at the harvesting of specialty crops.

Where the production of large quantities of specialty crops on new projects is contemplated, market outlets should be carefully determined before the project is set up. A delicate balance often exists between production and consumption of such crops, which a decided increase in production would destroy. Disturbance of the equilibrium usually causes wide price changes. A large increase in production would probably cause great difficulties both for the new farmers as well as for other farmers already producing that crop.

Although there are large numbers of unemployed industrial workers, an already over-burdened agriculture should not be expected to assimilate many of them. Rather than for the Government to encourage "back to the land" movements which tend to increase the supply and decrease effective demand for agricultural products, it would seem more logical to encourage existing industry, and to foster, particularly, the establishment of new industries to produce goods and services for which there would be a large public demand. The development of new industries may offer a more important method for the solution of the unemployment problem than industrial decentralization, and appears to be worthy of much consideration.

To summarize, integration of agriculture and industry should offer certain benefits. Irrigated projects often present conditions favorable to such integration. As conditions vary widely between irrigated areas, however, the adaptability of each area to such a plan should be judged individually on the basis of both economic and social values.

CHARLES P. WILLIAMS,[24] M. AM. SOC. C. E. (by letter).—A clear and convincing argument regarding what may be accomplished by the co-ordination of agriculture and industrial development, is contained in this paper. In the development of a large irrigation project the economic phases constitute a difficult and paramount problem. Of the irrigation projects built by the U. S. Bureau of Reclamation none can be considered, in itself, a commercially feasible investment. A project that cannot return the construction cost, without interest, within twenty-five years or more, cannot be considered commercially feasible. By no means does it follow that the investments were not justified. Incidental to the agricultural project, towns developed within the irrigated areas, with small mercantile stores of all kinds. There were established sugar factories, alfalfa meal mills, flour mills, creameries, cheese factories, canning factories, packing houses, and other small industries of various kinds. The benefits of the project were not confined to the irrigated area. A market was created for materials and supplies manufactured outside the project. The prosperity of such projects undoubtedly would be greatly increased by the introduction of other industries for supplying not only existing local needs, but also the increased demand created by the increased population.

In the paper, attention is called to the tendency toward the decentralization of industry. Such decentralization has been due, no doubt, not only to the greater economy of relatively small production units, to which the authors call attention, but also to the very high value of land in, or immediately adjacent to, large cities, and the consequent high value of plant sites, high taxes, and necessarily higher wages, due to the increased cost of living, for employees. Such decentralization, of course, has been on the initiative of the plant owners and management. Incidentally, labor has benefited by a lowered cost of living and more agreeable and healthful living conditions.

---

[24] Project Engr., Ambursen Eng. Corporation, Possum Kingdom Dam, Mineral Wells, Tex.

The marked increase in unemployment during the relatively prosperous years 1923 to 1929, inclusive, is discussed by the authors, as well as the percentage of decrease in labor forces and the concurrent percentage of increase in production, in each of nine important industries, during the period, 1923 to 1927, inclusive. Various examples have been cited of the remarkable increase in efficiency in various industries by the introduction of machines and more efficient methods, thus reducing the labor necessary, and adding greatly to the army of the unemployed.

The authors are of the opinion that the plan proposed, if adopted generally, would be very effective in reducing unemployment. The writer doubts the validity of this conclusion unless other measures, not mentioned by the authors, are taken. The economic structure of the United States is a very intricate and complicated system, and a complete and comprehensive discussion of the causes of depressions and recoveries is obviously far beyond the scope of this discussion. However, there are certain basic principles affecting the system which, to the writer, appear to be evident.

Undoubtedly, there are many factors which contribute to unemployment. One very important factor, if not the most important, is the introduction of machines and more efficient methods, thus reducing greatly the number of men necessary for the accomplishment of any industrial work. However, no sane man would advocate the discard of machines, or the return to less efficient methods. Even greater efficiency is desirable wherever possible. The problem is to determine how efficiency can be retained, and even increased, and, at the same time, how to eliminate unemployment, or at least, to reduce it greatly.

Assume a country in which there is such industrial and vocational balance that all men capable of working are employed and that all are receiving such just compensation as enables each to satisfy his needs of goods produced and services rendered. Now, let machines and more efficient methods be introduced to such extent that the total number of man-hours of work, in the country as a whole, necessary for the production of those things which before had been produced, and the rendering of the services before rendered, are reduced, say, 10 per cent. If then the industrial and vocational balance is to be maintained, one of the following two plans, or a combination of the two, must be adopted:

(*A*) The total number of hours of work of those engaged in production or service may be reduced 10%, each individual receiving such compensation as will enable him to continue to satisfy his needs of goods produced and services rendered; or,

(*B*) The number of hours of work per individual and the wages or salaries per individual, in the industries and vocations in which machines and more efficient methods have been introduced, may be retained as before, and the number employed may be reduced to that necessary for the same amount of production and service as before. Those not retained in these industries and vocations may be employed in new industries or services, with appropriate hours of labor and appropriate compensation, or in old industries or services in which the forces employed therein are insufficient to supply the demand for the products or services.

Under Plan (*A*), the cost of production and services, prices, ability to purchase, and profits will remain the same as before. The only advantage will be that: (1) All are employed as before; (2) every one will be able to enjoy the same comforts as before; and (3) the workers will have more leisure for recreation, mental improvement, social activities, and similar avocations.

Under Plan (*B*), each of the workers retained in the former industries and vocations will receive the same wage or salary as before. However, the cost of production and service will be reduced, prices can be reduced, and the worker can buy the products and services before purchased for less than the sum originally expended therefor, leaving a part of his earnings for the purchase of goods produced in the new industries and of the new services introduced. Likewise, those employed in the new industries and vocations will be able to purchase their proportionate parts of the goods originally produced and the services originally rendered, and also the products of the new industries and the services of those in the new vocations.

Plan (*B*) evidently is preferable to Plan (*A*). Under Plan (*B*), a higher standard of living will result. Owners of industries may receive the same profits as before, but at a higher percentage, or they may receive even greater profits if not all the decreased cost of production is applied to a decrease in prices.

Due to the very great reduction in labor needed in industry in recent years, it probably would not be possible to provide sufficient work in new industries and new vocations to reduce unemployment greatly. Such great reduction could probably be accomplished only by the combination of Plans (*A*) and (*B*).

In the plan of combined agricultural and industrial development, suggested by the authors, it is proposed that the workers be employed part-time in the industrial plants and part-time in agriculture. Agriculture is not a new industry; neither is agricultural production insufficient to supply the demand for agricultural products. The decrease in the hours of labor per man in industry would increase the number of men employed in industry, but if the reduction in hours of labor per man in industry is applied to agricultural production, to the same extent would farm labor by those engaged primarily in agricultural pursuits be reduced.

The writer does not wish to be understood as being of the opinion that the Madera District would not be benefited by the plan proposed by the authors. He believes that it would be. More particularly would the industrial workers be benefited by being occupied part-time in healthful, outdoor work, as well as by obtaining increased compensation. As a means of reducing unemployment, however, he believes that it would have little, if any, value.

The writer is of the opinion that, although the co-operative plan of gardening might result in greater efficiency, the allotting of individual tracts to workers would be more beneficial for the reasons stated by the authors. In this case, it is believed that efficiency is of less importance than the psychological effect. It would be desirable to have a demonstration farm where the men could work for a time until they become acquainted with effective agricultural methods. At first, this farm could be of large area (embracing the entire 25 000 acres, in the case of the Madera District). Individual allotments could then be made therefrom as the men become competent to conduct their own operations efficiently. The stabilizing influence, to which the authors refer, would be much greater if each man had a proprietary interest in his own individual tract than if his work were on a co-operative basis. As far as conditions would permit, each could live on his tract and could establish a permanent home on it. It is true that a centralized plan would be necessary, but it need not be co-operative, except for single men and those lacking agricultural training.

The authors propose that the managing, and presumably the financing of the industrial gardens be by the several industrial companies. The writer believes this to be inadvisable. Some industrial owners may be philanthropic and altruistic, but, in general, their chief aim naturally is to secure a maximum profit. Company farms, like company stores, and large tenant plantations might become a force for economic slavery. The agricultural unit, including houses for workers, could easily be made a State, or National Government, self-liquidating project, financed in a manner similar to the operation of the Federal Housing Administration, the manager, agriculturist, and all assistants being State employees.

ERNEST P. GOODRICH[25] AND CALVIN V. DAVIS,[26] MEMBERS, AM. SOC. C. E. (by letter).—In closing, the writers re-emphasize the existing needs for the economic re-adjustments outlined in this paper: (1) Technological advances are continuing to increase unemployment; (2) the workers thus displaced have, in most cases, no secondary means of support; (3) the overcrowded and restricted conditions in many industrial cities prevent any constructive use of idle time; and (4) the accumulated national loss resulting from this idle time is such a staggering value that almost any means, no matter how drastic, would be justified to prevent it. Consider, for example, a fair measure of this loss. At the nominal unit rate of $1 000 per worker the annual loss to the country, with 10 000 000 persons idle, would be $10 000 000 000. From a banker's viewpoint the prevention of this loss would be worth an investment of $100 000 000 000, or approximately three times the national debt. This is a challenge to engineers.

---

[25] Cons. Engr., New York, N. Y.

[26] Formerly, Chf. Engr., Ambursen Dam Co., Inc., New York, N. Y.

There are indications that the Medical Profession is already aware of the need for the social changes recommended by the writers. For example, Dr. Alexis Carrel has written:[27]

> "There have been in the past industrial organizations which enabled the workmen to own a house and land, to work at home when and as they willed, to use their intelligence, to manufacture entire objects, to have the joy of creation. At the present time this form of industry could be resumed. Electrical power and modern machinery make it possible for the light industries to free themselves from the curse of the factory. Could not the heavy industries also be decentralized? * * * Men would live in small communities instead of immense droves. Each would preserve his human value within his group. Instead of being merely a piece of machinery he would become a person."

The writers are in accord with Mr. Jacobs and Mr. McIver that this entire matter should be approached from an engineering angle. Engineers should be willing to assume a large measure of responsibility during the transition period.

The suggestions and analyses presented by the writers were not submitted as a possible cure-all for the problems outlined in the foregoing; these were intended to show by one specific example the possible benefits that could be realized from correlating the conservation of natural resources with industrial and economic adjustments. Conservation programs, such as are now (1938) under way in the arid regions of the West, could have as their larger objective the ending of unemployment. The investment in each project, in a sense, could be considered as an increment of the total that would be required to capitalize the time now being lost during depressions. Mr. Williams makes a point in this respect by indicating the over-all economic effects of the projects built by the U. S. Bureau of Reclamation even if many of these projects would not be commercially feasible investments when considered individually. Add to these existing benefits the partial elimination of unemployment, or, as Mr. Williams prefers to call it, furnishing a supplementary means of income during slack periods, and the accumulated benefit values will be many times the project costs.

Improvement, of course, cannot be brought about quickly; it will be rather a matter of slow growth. A long period of preparation, co-ordination, and training will be required, as suggested by Mr. Jarvis. It is unlikely that industrial growth will parallel colonization and agricultural development, as suggested by Mr. Gray; the writers are of the opinion that factories will follow only after the country is fairly well developed.

The writers intended to emphasize the need of a better balance between agriculture and industry in a given area rather than complete self-sufficiency as inferred by Mr. Gray and Mr. Jacobs. As Mr. Ferris so ably stated, there has been a mining process in some areas which has drained them of both human and material resources. In some cases, decentralization will help to restore, and in others establish, a more balanced economy.

CONSTRUCTION AND TESTING OF HYDRAULIC MODELS, MUSKINGUM WATER-SHED PROJECT

BY GEORGE E. BARNES[1], M. AM. SOC. C. E., AND
J. G. JOBES[2], JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. G. W. HOWARD, F. W. EDWARDS, T. T. KNAPPEN, RALPH W. POWELL, AND GEORGE E. BARNES, AND J. G. JOBES.

SYNOPSIS

Hydraulic model studies were conducted on eleven of the dams for the Muskingum Water-Shed Project, north of Zanesville, Ohio. This paper describes the laboratory facilities used in the tests, and the more important features of model fabrication, operation, and test procedure. The time and personnel required, and the cost of doing the work are given. An effort is made to present a picture of the physical equipment and organization required, and also the cost of securing results on a well defined, although not necessarily typical, program of model studies. It is believed that such material, as distinct from technical findings alone, has not formerly been made available to the extent desired by the profession. Thus, more discussion is devoted to the manner in which the work was done, than to a detailed analysis of the test measurements. However, certain selected test observations of special importance, which are considered to be of general interest as well, are presented herein.

METHOD OF ATTACK

In each of the eleven studies, a working model simulating the outlet works, spillway, or other features governing hydraulic performance, was constructed from preliminary drawings of the dam. The general purpose of all tests was: (1) To observe and record the behavior of the model, built in

---

NOTE.—Published in December, 1936, *Proceedings*.

accordance with the preliminary design; (2) to determine revisions necessary or desirable for optimum performance; and (3) to revise the model to complete or substantial agreement with the final design and to make complete record tests under the full range of flow conditions anticipated for the prototype.

The laboratory personnel was given the relation between tail-water stage and discharge at each site, based upon channel studies. In certain cases, where considerable variation in stage might be expected at a given discharge, the best performance was demanded only for most frequent operating conditions, good performance for less frequent circumstances, and safe operation under circumstances likely to occur only at rare intervals. Adequate discharge capacity and safety were of first importance.

The models were constructed with surfaces in contact with the water (except non-essential detail) similar to the proposed structure. The models were not distorted, and were built to the same vertical and horizontal scale, varying from 1:20 to 1:40. Each model included some or all of the following elements: (*a*) Reservoir approach topography at the control works; (*b*) intake tower and gates; (*c*) outlet conduits or tunnels; (*d*) stilling-basin; (*e*) outlet channel; and (*f*) spillway.

The laboratory studies extended from August 1, 1934, to June 20, 1935. They began immediately after the preparation of the official "Plan of Flood Control and Water Conservation Reservoirs" by the United States Engineer Office of the Zanesville District, and were continued throughout the design period. As the basic data for design were supplemented by field measurements and revised by analysis, and as laboratory test data accumulated, there was a constant rotation of data between the office and the laboratory during this interval. When acceptable performance for stipulated operating conditions was secured in the model, record drawings of the final model were put in the hands of the designers. These drawings were supplemented by a final report giving a complete record of all tests for that model.

LABORATORY FACILITIES

The model studies were made in the Warner Hydraulic Laboratory of the Department of Civil Engineering, Case School of Applied Science, in Cleveland, Ohio. This laboratory includes two flumes, both of which were used in the work, and the larger one of which was added specifically for these tests. Fig. 1 is a longitudinal elevation of the circulating system, showing the metering devices and the flumes with essential accessories.

The laboratory occupies a total of 6 000 sq ft of floor space on two floors of a modern building, with a trucking entrance on the ground floor and a 3-ton traveling crane for equipment and material handling. From a 50 000-gal recirculating reservoir under the ground floor, a battery of three centrifugal pumps, operating in parallel, with a total capacity of about 7.5 cu ft per sec, deliver through a 10-in. common header to a constant-level tank on the second floor, or to the supply mains direct, if desired. Flow from the constant-level tank is through a 12-in. or a 4-in. supply line, each equipped with a Venturi tube, the flow being registered with indicating, recording, and totalizing meters. The metered supply reaches the River Flume on the ground floor through a 10-in. riser, the discharge from the flume being returned to the recirculating reservoir. On the second floor, the Experimental Flume is fed by a 10-in. take-off from the riser, or from a 6-in. take-off and weir box.

Discharge from the experimental flume on the second floor reaches the reservoir through a 10-in. return, or may be passed through any one of six volumetric measuring tanks, each 6.0 ft in diameter and 10.0 ft deep, arranged in pairs, with flipper devices for continuous running to calibrate the meters or measure the discharge, and each equipped with telescopic level readers and quick-opening valves through which water is returned to the reservoir.

FIG. 1.—LONGITUDINAL ELEVATION OF HYDRAULIC LABORATORY (NOT TO SCALE)

Both the second-floor experimental flume, with glass section, and the river flume on the ground floor, are equipped with adjustable tail-gates and with numerous piezometer connections. Each separate model requires a newly built piezometer assembly, leading in each case to a battery of open buckets in which levels are read by a hook-gage traveling on a carefully leveled rider bar. Each separate model, likewise, requires newly set rails supporting point-gage bridges, or sounding devices for measuring scour.

Required flows are set by valve manipulation and indicated by either the 4-in. or the 12-in. Venturi tubes. At low flows, a U-tube manometer containing carbon tetrachloride is used in tests as it gives much greater deflections and greater precision in reading. To insure minimum error, the 4-in. and the 12-in. meters are rated by volumetric measurement. The models for the Wills Creek, Charles Mill, Mohawk, Dover, Mohicanville, and Pleasant Hill Dams (see Fig. 2) were tested on the ground floor and the models for the Tappan, Clendening, Piedmont, Senecaville, and Bolivar Dams were tested on the second floor.

Any description of laboratory facilities needed for model studies would be decidedly incomplete without mention of the shop facilities, tools for maintenance work, and the fabrication of special instruments, or other devices required for a wide range of purposes. In a large city such as Cleveland, the availability of industrial shops is an added asset. Furthermore, room is needed for the preparation of drawings, filing of records, and reference material

TYPES OF MODELS

requirements, dissimilarity between structures is occasioned partly by the fact that operation of the several works was planned so as to be interrelated, and the performance of one outlet, in certain cases, affects another. These circumstances result in a great variety of hydraulic problems to be solved in design, and the model studies, therefore, vary in character to a commensurate extent.

For each dam, the outlet works terminates in a stilling-basin in which an hydraulic jump is formed, to dissipate the energy of conduit discharge. Since, in any case, spillways on these dams discharge under emergency conditions only to safeguard embankments, model spillways were studied in the laboratory only for those few dams where the confluence of spillway and outlet discharge occurs in such a manner as to affect, appreciably, the design of the spillway, the outlet works, or both.

The Wills Creek, Mohawk, and Bolivar models each include an intake tower with six control gates discharging through twin tunnels or conduits of horseshoe section, into a stilling-basin. The dimensions, heads, capacities, and tail-water conditions differ widely for the three dams.

The Clendening, Tappan, and Piedmont models each discharge through a single horseshoe conduit into a different type of stilling-basin. The Clendening, Tappan, and Piedmont Basins are similar to each other, but unlike

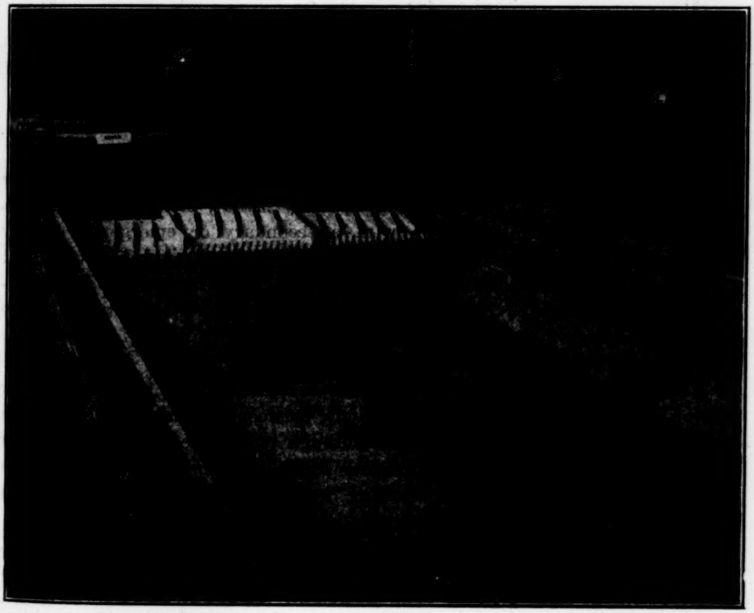

FIG. 3.—MODEL OF SPILLWAY AND OUTLET WORKS, DOVER DAM

those developed for other dams of the project. The distinctive feature is the rise of the curved apron below the portal to an elevation higher than the invert of the tunnel, followed by a parabolic drop to the floor of the stilling-basin. The formation of an hydraulic jump with relatively high tail-water and low tunnel elevation and discharge is thereby obtained.

FIG. 4.—MODEL LAYOUT, PLEASANT HILL DAM

The Charles Mill and Mohicanville models, as finally crystallized after substantial changes to the preliminary spillway layout, include short conduits through a solid masonry section with a secondary or emergency spillway immediately adjacent. The Senecaville model discharges through twin short conduits set in a gate-tower centered between adjacent twin over-flow sections, each surmounted by a Taintor gate. For Senecaville, the discharge from all outlets combines in a long paved channel with a steep grade leading to a stilling-basin, 400 ft (20 ft in the model) down stream.

The model of Dover Dam (see Fig. 3), simulates a solid masonry, overflow section, 338 ft long (9.66 ft in the model), between abutments, with eighteen gate-controlled, short, outlet conduits through it. These conduits are set in three batteries of six units each, at three levels. The outlet portals discharge over a curved apron between training walls into a stilling-pool which is required to be very shallow because of foundation conditions at the site.

The model of Pleasant Hill Dam (see Fig. 4), includes an intake tower, enclosing a vertical shaft, into which flood waters are discharged through six orifices, without control gates. The orifices are set at two different elevations, and are dimensioned to secure capacity which will predetermine the reservoir rise automatically. The model shaft discharges at the base through a constricted throat (for the purpose of maintaining a plunge pool in the shaft) into a 6-in. (15-ft on a 1:30 scale), circular tunnel, and blow-off gates are provided at the tower base, as well as temporary openings for diverting water during the construction period. The spillway is of the shaft type with a circular crest, 2 ft 8 in. (80 ft) in diameter, surmounted by piers to eliminate vortex action, and with its ogee surface converging to an 8-in (20-ft) circular shaft and 90° bend to the horizontal. The model tower and spillway tunnels meet in a wye junction to form a tunnel (horseshoe section) 8 in. (20 ft) in height and width, leading to a stilling-basin below the dam.

Model Fabrication

From the dimensions on the design drawings the Laboratory Staff prepared detailed model drawings for the fabrication of the several elements, and also layout sheets to guide assembly and erection. In making the models, skilled labor was employed in the laboratory and shop. Certain units were made for a price by commercial organizations in Cleveland. In the special instance of the wye-tunnel junction for Pleasant Hill (required to be made of a transparent material so that flow inside the junction could be observed and photographed), the piece was fabricated at the University of Iowa, at Iowa City, Iowa, from drawings prepared at Case School, and then shipped to Cleveland for erection. Speed was essential and all available facilities were needed. Where complex details had to be reduced to model dimensions, as, for example, in the gate-towers, and tunnel and portal sections, the model drawings were made to full model scale. Topography in the model reservoir and in the channel below the dam was reproduced in the model by inundated sand fill, topped with a 1½-in. mortar coat, placed between sheet metal templets cut to the proper transverse profile and set at several stations on the center line of the works. A tinsmith cut these templets from full-sized paper patterns. The original pencil fabrication and layout drawings were usually handled by the craftsmen working on the model, and due to the different scales required for the drawings, it was not always feasible to establish a uniform size for the sheets. Experience indicates that it might be preferable to maintain a uniform size for filing and to work from blue-prints, since the drawings suffered considerably in the handling.

To secure the complicated shapes with reasonable accuracy and speed, it was found best to work in sheet steel. The model tunnels and gate-towers, therefore, were made from welded 16-gage material. The Morning Glory spillway was spun from sheet aluminum, on a laminated solid wooden core, accurately turned to shape. The curvature in the tunnels was made as a series of short tangents. The joints between tunnel sections were male and female with bolted flanges. In forming the multiple short conduits—as for the Dover, Charles Mill, and Mohicanville Dams—a box-like steel shell formed the floor, ceiling, and the side walls of the outermost conduits. Individual conduits were then formed by wood-block inserts or piers fashioned by a pattern-maker with snug fit between floor and ceiling. The gates for all dams were vented immediately down stream. These vents were reproduced accurately in the models with welded steel, with openings carried through risers, headers, or stacks as in the prototype, either to scale or slightly larger. The stilling-basins were usually formed with wood floor, walls, baffle-piers, and terminal sill. Where the side walls were warped, it was easier to secure proper dimensions with 22-gage galvanized sheet metal, or some comparable commercial product. Where changes were not anticipated the walls and floor of the stilling-basin were formed in mortar.

Numerous piezometer connections were installed along the floors of the conduits and at other points where pressure readings were desired. Unless piezometer openings are mechanically true, and unless the surfaces in which they are set are absolutely smooth and undistorted, false readings will be secured. For these models the best piezometer connection was found to be made by brazing a solid lug about 1 in. long to the under side of the steel floors, and drilling either a single $\frac{1}{8}$-in. hole through it in a direction normal to the surface, or three of such holes, and dressing the opening at the surface with a slight radius. The opposite end of the lug was tapped for the insertion of a $\frac{1}{4}$-in. or a $\frac{3}{8}$-in. pipe leading to the piezometer buckets. On the surface of the Morning Glory spillway of the Pleasant Hill model seven pairs of piezometer openings, diametrically opposed, were connected through similar lugs to copper tubing leading to a piezometer panel on which was mounted 0.5-in. transparent tube through which the pressure gradient was read directly against paper scales. It should be remembered that piezometers record the

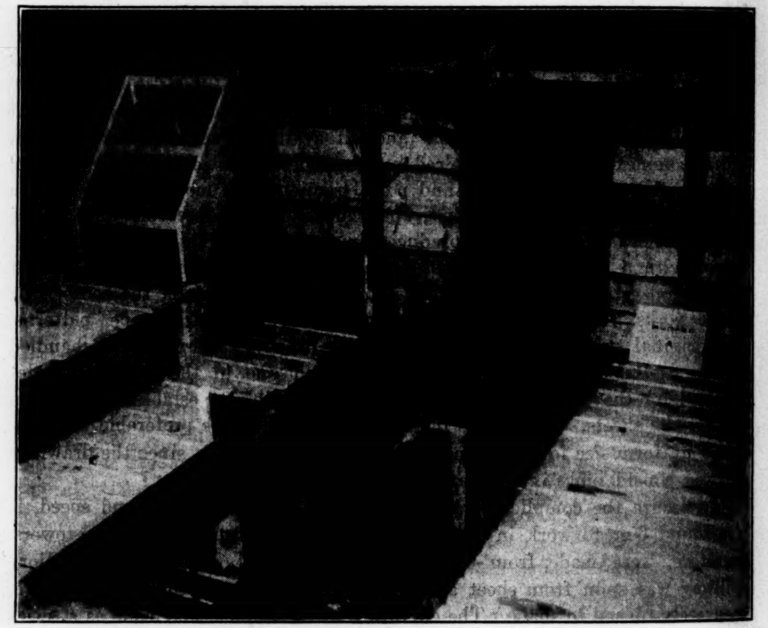

FIG. 5.—MODEL OF INTAKE AND TWIN TUNNELS, MOHAWK DAM (ORIGINAL DESIGN BEFORE REVISIONS)

pressure and not the water depth where curvilinear flow exists in a vertical plane. Of all the measurements taken, piezometer readings were most difficult and unsatisfactory.

Fig. 5 shows a model of sheet steel with the intake ceiling elliptical in profile and of transparent material. The gates are steel flats, sliding in grooves in the wood division piers, and vented through rectangular slots and stacks. The tunnels are 20 ft high (model scale, 1:40). The complete model for the Dover Dam to a scale of 1:35 is shown in Fig. 3. Typical model construction is shown in Fig. 6[4]. The Bolivar tunnels are 16 ft high to a scale of 1:40. Typical of the stilling-basins for Clendening, Piedmont, and Tappan, is the model shown in Fig. 7.

FIG. 6.—TYPICAL MODEL CONSTRUCTION, BOLIVAR DAM

FIG. 7.—MODEL OF STILLING-BASIN, CLENDENING DAM

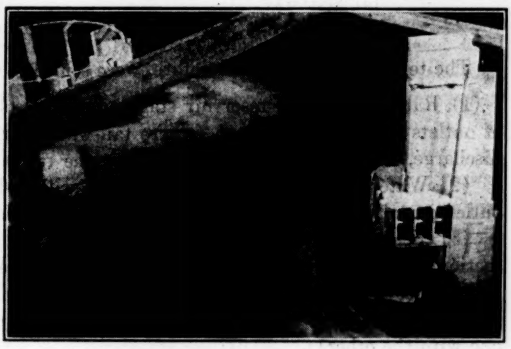

FIG. 8.—MODEL OF INTAKE TOWER, PLEASANT HILL DAM

Some of the most complex model fabrication was required in the case of the Pleasant Hill Dam. Fig. 8 shows the model intake tower of welded steel sheet. The Morning Glory spillway of spun aluminum with piezometer connections is shown in Fig. 9(*a*). The wye transparent junction and steel horseshoe tunnel are exposed for their full length to provide access to piezometers. The wye is shown in Fig. 9(*b*).

MEASUREMENTS

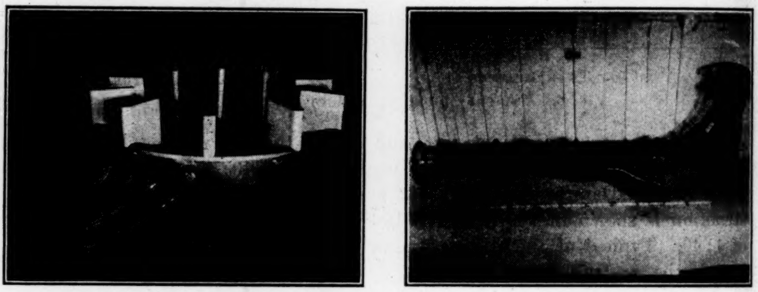
For each of the eleven dams certain features of operation and performance were studied, including:

(*a*) The relation of reservoir stage to discharge, for various combinations of outlet openings;

(*b*) The distribution of energy losses;

(*c*) The capacity and behavior of the spillways; and,

(*d*) The performance of the stilling-basin, with particular reference to the variation in tail-water level at a given discharge, or the unsymmetrical discharge from the multiple outlets.



(*a*) SPILLWAY (*b*) TUNNEL JUNCTION

FIG. 9.—TYPICAL MODEL CONSTRUCTION, PLEASANT HILL DAM

The test measurements, therefore, were aimed to secure the following data:

(1) Rating curves of reservoir stage against discharge for all combinations of outlets open or partly open (where tail-water variation affected the rate of discharge, rating curves were secured for the range of tail-water levels);

(2) Water surface profiles through the stilling-basin, extending from the outlet portal through the hydraulic jump to the channel below;

(3) Velocity traverses showing the distribution of velocities across various sections in the stilling-basin, and in the channel below;

(4) Scour (with the sand bed of the outlet channel screeded level before a test run, cumulative scour over an hour's time was measured to compare tests, one with the other);

(5) Flow conditions, recorded by photographs and motion pictures;

(6) Observations without measurement (the effect of rising tail-water on the hydraulic-jump performance was recorded as observed by eye for small increments of rise);

(7) Check surveys to determine the actual measurements of the models at various times as against the measurements to which they were set (in some

cases swelling wood or settlement of supports made it necessary to re-set the model; the actual dimensions of the model tunnels and outlets were recorded); and, finally,

(8) Record tests.

The latter (Item (8)) were so-called formal tests conducted with all the measurements required to determine the behavior under stipulated operating conditions. They included hydraulic gradients through the structure, the upper pool elevation and discharge, the water-surface profile of the hydraulic jump, the distribution of velocities in the stilling-basin, and the topography of scour at the end of an hour's run.

Model Operation

For taking measurements it was found convenient to furnish the laboratory operators with mimeographed sheets, there being a separate form for the: Rating curve; water-surface profile; velocity traverse; hydraulic gradients; scour sheets; and daily diary.

In operation, two men could usually handle the model on an 8-hr shift, one acting as reader and the other as recorder. When the model was being built or dismantled, skilled and unskilled labor was employed in addition. The laboratory operated continuously on a 24-hr, three-shift basis for about seven months. This continuous operation and accumulation of data kept about ten draftsmen busy, on an 8-hr basis, plotting, computing, and recording all measurements and model details, and preparing fabrication drawings for new models.

For a record test, the sand bed below the stilling-basin was first screeded level to the desired contour. From a 2-in. flood line, water was admitted slowly at the tail-gate to approximate tail-water depth for the intended discharge, so that the initial scour during the run would be slight. The proper flow was set by the meters, and the reservoir level and tail-water level were brought to equilibrium. All piezometers were blown free of air and stabilized. The hydraulic gradients were then recorded, water-surface profiles were taken in the stilling-basin with a point-gage and the distribution of velocities was recorded by Pitot tube or Bentzel tube in the stilling-basin and below the terminal sill in the outlet channel. At the end of an hour's run, the flow was stopped, the reservoir was allowed to empty, and the lower pool was drained to expose the sand bed, which was then measured with a sounding rod to record the depth and location of scour.

Scour measurements were taken as an index by which performance between tests could be compared roughly, since it denoted concentration of high velocities or persistent eddies and whorls along the bottom of the channel. Excessive or irregular scour in any case showed poor distribution of terminal velocities. From velocities at two-tenths and eight-tenths of the depth, the discharge was computed by ordinary stream-gaging methods to check by agreement with Venturi meter readings.

For Wills Creek, a preliminary model to a scale of 1:40 was superseded by a final model to a scale of 1:25. For Charles Mill, a large scale (1:20) model was used for conduit and stilling-basin studies only, followed by a 1:30 scale model complete with spillways.

Time, Personnel, and Cost Requirements

Fig. 10, "Laboratory Schedule", shows the dates between which model erection and model testing occurred. The interval shown for erection and testing does not include time for preparing drawings, for the fabrication of model parts, or for handling and digesting test results. As a rule, no time elapsed between clearing the flumes of one model and erecting another. The vertical lines in Fig. 10 indicate the man-hours for that week's payroll, including all operations. Rates for engineering assistants (draftsmen, computers, model builders, and model operators) ran from $0.60 to $1.50 per hr, limited to a 40-hr week. Rates for skilled labor (machinists, carpenters, cement finishers, pattern-makers) ran at the prevailing local scale, from $1.00 to $1.25 per hr, limited to a 30-hr week.

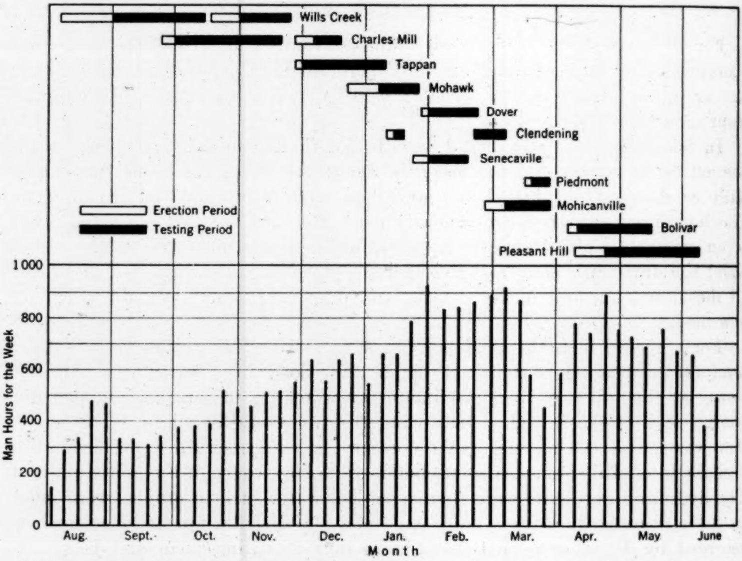


Fig. 10.—Laboratory Schedule, Showing Dates Between Which Model Erection and Model Testing Occurred

The direct cost of materials and labor for the several models is shown in Table 1. It includes a total of about $1 800 for blueprinting required for the several reports and $1 100 for photographic prints used in the reports. The power consumed in pumping totaled about 20 000 kw-hr. To these data should be added approximately 40% to cover rentals, supervision, miscellaneous services and supplies, travel and consulting expenses, and the salaries of three engineers from the Zanesville U. S. Engineer Office stationed at the laboratory. Included in the 40% is the cost of the river flume ($1 250), which was installed specifically for these tests and transferred to Case School as part compensation for the work.

TABLE 1.—Direct Labor and Materials Involved in Model Testing

Structure (see Fig. 2)	Scale of model	Units tested	Costs		
			Labor	Materials	Total
Wills Creek	1:40 1:25	Intake, twin tunnels, stilling-basin Intake, twin tunnels, stilling-basin	$4 650.59	$1 382.48	$6 033.07
Charles Mill	1:20 1:30	Outlet conduits, stilling-basin Outlet conduits, overflow section, stilling-basin, spillway	3 010.00	977.81	3 987.81
Tappan	1:20	Tunnel, stilling-basin	935.94	277.87	1 213.81
Clendening	1:20	Tunnel, stilling-basin	972.31	262.87	1 235.18
Piedmont	1:20	Tunnel, stilling-basin	398.03	131.34	529.37
Mohawk	1:40	Intake, twin tunnels, stilling-basin.	2 468.06	1 106.39	3 574.45
Senecaville	1:20	Outlet conduits, Taintor gate sections, outlet channel, stilling-basin	1 106.05	236.46	1 342.51
Dover	1:35	Spillway section, outlet conduits, stilling-basin	2 038.85	960.52	2 999.37
Bolivar	1:40	Twin intakes, tunnels and stilling-basin	1 231.50	580.02	1 811.52
Mohicanville	1:25	Outlet conduits, outlet channel, stilling-basin, spillways	1 546.56	499.35	2 045.91
Pleasant Hill	1:30	Intake tower, spillway tunnels, stilling-basin	3 167.83	1 574.40	4 742.23
Beach City	....	Preliminary drawings for model	33.00	....	33.00
Cost	......	....	$21 558.72	$7 989.51	$29 548.23

Exclusive of the building, a 50 000-gal. reservoir, the general plant, shop, and tools, the permanent investment, installed, for the principal items of the fixed equipment used for the tests is:

Three motor-driven pumps and controllers	$ 3 400
Major piping and valves	1 750
Constant level tank	300
Venturi tubes and meters	600
Experimental flume (3 ft 0 in. by 3 ft 0 in. by 90 ft 0 in.) with drains	1 300
River flume (5 ft 6 in. by 12 ft 0 in. by 44 ft 4 in.)	1 250
Measuring tanks	2 400
Total	$11 000

Caution must be used in comparing the cost of model studies, one with the other, because they are likely to be unrelated in character. The costs shown are those for a concentrated extensive program of studies generally similar and related, under a carefully planned and rigorous schedule. Furthermore, for these studies, work ceased the moment major decisions on design could be made, and the models were built in an economical manner for this immediate purpose only.

Operating Difficulties

Mechanical imperfection of the models themselves, together with the physical difficulty of taking precise measurements in all laboratory work, may seriously affect the results of an hydraulic model study, if these factors are under-rated or their significance ignored. Some of these factors deserving special consideration are: Discharges, piezometer readings, points of filling, orifice coefficients, joints and connections, warping, settlement, water-surface elevations, velocity measurements, and entrained air.

Discharges.—The small geometric scales necessary, require a large ratio of prototype flow to model flow, necessitating the accurate measurement of discharge. Where a weir is used, calibration should be directly by volume or weight if possible. Otherwise, proper precautions must be followed to insure that the weir corresponds in setting to the original by which formulas have been derived. With the Venturi meter, direct reading may be obtained at about full capacity with ordinary differential manometers. As previously noted, it is much more satisfactory with lower flows to magnify the deflections of the manometer by the use of a lighter liquid, such as, carbon tetrachloride. The specific gravity of the carbon tetrachloride must be determined carefully and frequently, and the glass tube should be at least 0.5 in. in diameter for easy cleaning and to avoid the effects of surface tension on the meniscus.

Piezometer Readings.—Where high velocities occur, piezometer readings are the most difficult measurements to obtain most accurately. A piezometer orifice with $\frac{1}{4}$-in. hole and $\frac{1}{16}$-in. radius of rounding is recommended for standard practice by C. M. Allen, M. Am. Soc. C. E. For smaller pipe sizes, he suggests a $\frac{1}{8}$-in. hole with $\frac{1}{32}$-in. radius.[5] The latter suggestion was adopted by the writers for model tunnels about 4 in. to 8 in. in diameter. The relation between discharge in the prototype and that in the model depends on the ratio, *n*. Since *n* must be determined by piezometer readings their importance and the care to be exercised in the fabrication of piezometer connections cannot be over-emphasized.

Points of Filling.—That point at which the model tunnel ceases to flow partly full and begins to flow completely filled, is difficult to determine. Even where this point is determined accurately in the model there may be some question as to whether or not the prototype will behave in exactly the same manner.

Orifice Coefficients.—The use of models in which orifices are involved raises the question as to how the coefficients are affected by actual size. Tests covering small orifices show a variation in the coefficient with the actual size of opening.

Joints and Connections.—As few joints as possible in a model appears to be desirable, inasmuch as these joints affect flow conditions both up stream and down stream with consequent breaks in the hydraulic gradient, as shown in the piezometer readings. A smooth hydraulic gradient is desirable in order to obtain the value of *n* for the model.

Warping.—It is extremely difficult to prevent warping in wooden models. Slight warping often produces incorrect flow conditions, which affect the results seriously. Many methods of water-proofing have been tried by the different hydraulic laboratories. The use of celluloid dissolved in banana oil, and the use of aluminum foil have been tried.

---

[5] "Piezometer Investigation", by C. M. Allen, *Transactions*, A.S.M.E., May 15, 1932.

Settlement.—Settlement of the sand base under mortar surfaces leaves the templets exposed and elevations in error so that often it is necessary to rebuild the model after it has been in use. If the sand base is thoroughly inundated prior to placing the mortar surfaces, and not permitted to dry out, this difficulty is kept at a minimum.

Water-Surface Elevations.—Water-surface elevations are difficult to obtain, and care in leveling the base rail and in checking of the gage zeros, must be maintained at all times.

Velocity Measurements.—Velocity measurements in a model are difficult to obtain inasmuch as they usually cover a wide range, from considerably less than 1 ft per sec to greater than 10 ft per sec. For the low velocities the Bentzel meter, specially constructed Pitot tubes, and small current meters have all been used by the various laboratories.

Entrained Air.—Most hydraulic formulas are based on the assumption that water weighs 62.5 lb per cu ft. However, they do not hold exactly where the hydraulic jump, or where flow conditions in which air is entrained occur. Thus, any model that includes these flow conditions should have a factor of safety added greater than the minimum dimensions shown by the model tests.

OBSERVATIONS AND FINDINGS

In model studies, preliminary analysis is essential in order that time and money spent on laboratory manipulation may be minimized. The test measurements themselves are worthy of equally careful analysis and interpretation. Analysis of the detailed test observations, however, is beyond the intended scope of this paper, and the following discussion includes certain findings which are stated in general terms only, to give a brief picture of certain selected results.

The outstanding single result of tests was an improvement to all stilling-basins. In the case of single or twin outlet conduits, the typical features of the model basins are illustrated in Figs. 4 and 7. With the jet issuing from the portals between flaring side-walls over a curved apron, the models demonstrated, for these outlets, that the jump could be held with slight change in location on the apron, for all rates of discharge and corresponding tail-water levels, by block-shaped baffle-piers with stepped up-stream faces, anchored to the basin floor. For a given discharge, the jump appeared to be slightly more stable when the apron itself was stepped.

With excessive flare and batter to the side-walls, lateral distribution of the shooting flow on the apron was poor. In such cases the water failed to follow the flare, and lack of forward momentum at the side-wall permitted back rollers from the tail-water in the lower end of the basin, which skewed the jump to one side. The result was persistence of whorls, eddies, and concentrated high velocities at the exit from the basin. Similar behavior accompanied the presence of excessively high tail-water in any case. A low value of average velocity computed on the basis of high tail-water proved to be a deceptive index to flow conditions, if the jump itself was neither positive nor balanced.

In the models, good results were secured when the side-walls up stream from the jump were not flared more than 1 on 4 (preferably 1 on 5 or 1 on 6), and battered not more than 1 on 10. The parallel side-walls of the basin, below the jump, were battered as suitable for their construction as paved slopes or retaining walls, as the case might be. With tranquil flow instead of shooting flow, the slopes could be flatter without serious effect on performance, although slopes as flat as 4 on 1 produced eddies in some cases.

For structural or other reasons, the outlet tunnels for several of the dams were originally set lower than proved suitable for good performance with the coincident tail-water conditions corresponding to the several rates of discharge. In some cases, the tunnel was raised as a result of the tests; in others, where this was not feasible, a unique expedient solved the difficulty.

The Clendening stilling-basin has already been specially mentioned. In the original design, the tunnel invert was placed low, and high tail-water in the model drowned out the jump. To secure a good hydraulic jump without raising the tunnel, proper relation between momentum of outflow and tail-water depth was secured by passing the water over a humped apron (as described under the heading, "Types of Models"), through which a narrow gutter was cut for drainage. The hump was first built crudely with wooden flats in the model, and then carefully shaped for easy transition. This feature was also adopted, after trial, in the models for the Tappan and Piedmont Dams as well.

To reduce concentration of scouring velocities along the bed of the outlet channel, a low terminal sill with the up-stream face stepped, was placed at the end of the stilling-basin and was found to be the simplest and most effective, although other types were studied.

One expedient to reduce the length of stilling-basins was to carry the horizontal flare into the tunnel portals. In the first Mohawk model, with portal and tunnel height equal, the portal flare and increase in area resulted in the hydraulic control being shifted from the tunnel section at low flows, to the portal section at maximum flows. With the large portal flowing full at atmospheric pressure, the differential between the portal velocity head and the tunnel velocity head was roughly 20 ft. Consequently, negative head occurred in like amount in the tunnel. When the flare was omitted from the tunnels, and stilling-basin side-walls were adjusted to correspond with increased warp and flare, the hydraulic jump was unbalanced. The flare was restored, therefore, to the portal section, but the portal area (and negative tunnel head) was reduced by dropping the portal crown. Piezometer readings in the model disclosed the shift in the pressure gradient.

Finally, for all stilling-basins, tail-water stages were such that the depth in the basin much below the stream bed was, in general, found to be needless, and the model studies resulted usually in reducing the length or width of the basins, or both. Liberal size alone was found to be insufficient guaranty of adequate performance.

The true head between reservoirs and outlets is difficult to discover. For preliminary designs, outflow was predicated on head measured as reservoir elevation, minus portal invert elevation, minus the average depth at the portal. Actually, the head will be greater, since the jet from the portal is accelerated downward by gravity, and the pressure head on the apron is less than that caused by an equal depth of still water. The discrepancy between assumption and fact will depend on the sharpness of apron curvature and jet velocity. In the case of the Pleasant Hill model, the true head by piezometers appeared to have a value closer to reservoir elevation, minus portal invert elevation, minus one-half the depth. The model discharge was greater than anticipated and, in fact, substantially exceeded the required capacity, so that the original 20-ft tunnel and shaft was reduced to 19 ft, with incidental changes resulting in reduced cost of construction.

Another feature of the Pleasant Hill model was the transparent wye-junction through which flow conditions, much under discussion during staff conferences, could be observed and evaluated. With certain rates of flow (to occur in Nature at rare intervals), the model showed that discharge from the gate tower would enter the junction in such fashion as to climb the opposite wall and spiral completely around the interior face of the main tunnel.

The Bolivar model was operated with its portal submerged by the tail-water, as would be required for this particular dam at certain outflows, and when the Dover Reservoir, located down stream, is filled to crest level. Quick closure of the model gates caused a sudden inrush of air through the vents, the slug of air traveling down the tunnel to be released at the portal. Release of air was followed by a sudden rush of tail-water into the portal, with severe slap and shock. Disturbance also occurred with the gates stationary in a throttled position, provided the portal was submerged. The gates in the model, of course, can be closed almost instantaneously, whereas the mechanism in the actual structure will not permit any such rapid gate manipulation. Nevertheless, the model showed that it might be important to release the water through a few gates fully opened rather than through several in a throttled position, and to restrict the speed of gate closure.

With multiple short conduits through a masonry section, as for Charles Mill and Dover Dams, increase in capacity or improved lateral spread on the apron was attempted with conduits having a curved or offset ceiling profile, or horizontal flare, or both. The benefits, if any, indicated in the models were not considered commensurate with the probable cost of the more complex shapes and, in each case, the final models crystallized into conduits of simpler uniform rectangular section and liberal elliptical easement at the inlet, which appeared to be entirely suitable.

The size and position of training walls, and the shape of rock-cut benches by which spillway discharge could be directed with a minimum disturbance into the outlet channels, were studied in the Charles Mill and Senecaville models. Studies of alternate types of spillways were made for Mohicanville. The approach cuts and wing-walls at the inlet were improved in the models for Wills Creek, Charles Mill, and other dams.

Relation Between Capacity of Prototype and Model

To check the stipulated capacity of the outlet works at a given reservoir stage, it is necessary to convert the model discharge into corresponding flow in the prototype. Where gravity is the predominating factor in inducing flow, with comparatively slight retardation from friction, the flow in the model is directly converted to flow in the prototype by the $\frac{5}{2}$ power of the scale ratio. Such a conversion factor would be appropriate for overflow spillways, stilling-basins and (for simplicity, and on the safe side, for capacity), for short conduits. In long tunnels where frictional retardation has a great influence on discharge, it was difficult or impossible with these model scales and structures to secure an interior roughness factor, or Kutter's n, low enough to give the foregoing conversion factor where n in the prototype is to be 0.011 or 0.013. Consequently, it was necessary to determine the value of n for the model by observing, carefully, the hydraulic gradients in a straight section where uniform flow obtained. For example, the value of n for the model of the Mohawk Tunnels (1:40 scale) was found to be 0.0091, which indicates that the models, however smooth mechanically, are nevertheless too rough to simulate conditions in the prototype. However, knowing the value of n for the model, the corresponding flow in the prototype can be computed by Manning's formula, or by other accepted formulas. For these models too much confidence is not warranted in the experimental values of n, because the model tunnels are believed to be too short to establish uniformly good flow conditions.

Summary and Conclusions

The fact that hydraulic models cannot be made to reproduce, in exact miniature, all the phenomena that will occur in the prototype does not detract from their genuine utility. The performance of hydraulic models may be interpreted to great advantage by a designing engineer. It is obvious that certain of the foregoing findings could not be determined over the drafting-board, or by analysis alone, and that other measurements furnish the data for needed analysis. The model studies described in this paper were in the nature of check tests for the sole purpose of expediting the production schedule demanded of the Designing Staff for this project, by contributing a valuable supplementary method for attacking complex problems of hydraulic design. The tests more than saved their own cost by actually reducing construction expenditure, and, in addition, gave invaluable assurance as to the probable behavior of the finished structures of the Muskingum Water-Shed Project. It is hoped that the data presented herein may be helpful in planning other model studies of somewhat related character.

Acknowledgments

The model studies were conducted under the direction of the senior writer, with the junior writer assigned as Assistant in active charge of laboratory operation. W. A. Snyder, Junior Engineer, and L. G. Leach, Jun. Am. Soc. C. E., Junior Computer, were also stationed by the Zanesville Engineer Office at the Laboratory. The Laboratory Staff included G. Brooks Earnest, Assoc. M. Am. Soc. C. E., W. J. Hopkins, Jun. Am. Soc. C. E., and fifteen to twenty Engineering Assistants at the Case School of Applied Science. The co-operation of the Designing Staff throughout the work was most helpful.

DISCUSSION

G. W. HOWARD,[6] JUN. AM. SOC. C. E. (by letter).—In view of the increasing use of model studies and the corresponding increase in difficulties of construction and operation of models, this paper is extremely helpful in its presentation of the author's experiences in conducting the studies made in connection with the Muskingum Water-Shed Project.

It is doubtful whether the troubles that are encountered with piezometers can be over-emphasized. The authors state that, of all measurements taken, the piezometer readings were the most difficult and unsatisfactory. This is generally true in almost every study of the type discussed, where much use is made of piezometer readings. The general difficulty encountered is in fluctuations in the manometer tubes, caused by entrained air. To care for this factor, it is frequently possible to install bleeder valves at certain points in the line to permit correction of this difficulty and also to flush the lead line.

When there are excessive fluctuations in the tube, it is also possible to use several arrangements for dampening these fluctuations in an effort to obtain an average reading. One method is to choke the line, either by using a clamp or by a reduction in size of the line. Another method is to have a stilling-well, say, 9 in. by 9 in. by 15 in., into which the line is led before it is taken to the manometer tube or gage bucket. This second method has been found by the writer to be preferable to choking the line. However, any method for dampening fluctuations to obtain an average reading must be used with caution. Each gage should be investigated carefully to determine the time required for equilibrium to be reached, because inconsistencies in results can quite often be traced to a manometer observation made prior to equilibrium.

F. W. EDWARDS,[7] ASSOC. M. AM. SOC. C. E. (by letter).—Former papers on hydraulic investigations utilizing models have described briefly the laboratory equipment and the physical features of the models as incidental to the more detailed presentation of the test results. In this paper, the opposite is true. Two objectives are reached by this change: First, to other research workers, many hints on model construction and operation are given; and, second, to the designers who put into practical use the results of tests, some of the problems to be met and some of the limitations to be expected in model studies are presented, thus promoting better understanding between the research and the design groups.

It is proposed herein to add a few remarks on the economics of model investigations, to elaborate somewhat upon the operation difficulties listed by the authors, and to discuss the relation between the capacity of the prototype and the model as mentioned in the paper.

[7] Chf. of Hydr. Section, U. S. Engr. Office, 2d New Orleans Dist., New Orleans, La.

Economics of Model Investigations.—The cost of a model investigation is difficult to determine in advance. As emphasized by the authors, caution should be used in comparing the costs of different models. The construction cost for some types of models is relatively large whereas the operation cost of others is the major item. The cost of the construction of the first test set-up and of the operation of the first series of proposed tests may be estimated readily, but the results of the first few tests may change the nature of the entire future program. Before the completion of the study, it is often necessary to develop new instruments to obtain the results desired. Furthermore, models similar in character studied at one place during an extensive program (as were the Muskingum studies), will cost less on the average than a single model.

Offsetting the uncertainty of cost of a proposed investigation is the fact that model studies usually point to economies either by indicating inadequate designs, by directly reducing construction costs, or by both. Savings created by the elimination of unsafe designs are indirect and often cannot be evaluated accurately. However, there are many examples of reductions in construction cost, subject to accurate estimation, which were created entirely by model investigations.

An example of a model study which eliminated an unsafe design and, at the same time, reduced the estimated cost of the structure is that of the stilling-basin for the Conchas Dam which was completed at the U. S. Waterways Experiment Station, at Vicksburg, Miss. This study exposed a dangerous flow condition in the basin for the preliminary plan and led to the adoption of an alternate plan having a reported cost[8] of approximately $625 000 less than the original design. The cost of the model study was less than $10 000.

The estimated construction cost reductions which were made possible by the tests for the Muskingum Water-Shed Project are not known to the writer, but the general statement made by the authors, that "* * * the model studies resulted usually in reducing the length or width of the basins, or both," indicates that the money saved made the cost of the investigation appear insignificant. There are many other examples of great economies resulting from model experimentation.

Operation Difficulties.—Operation difficulties place definite limitations upon model studies. The recognition of these limitations is essential to proper analysis of the test results. The authors state that piezometer readings are the most difficult to obtain accurately. Of course, the importance of the various measurements depends upon the particular problem being studied, but the writer believes that, ordinarily, velocity measurements in the type of model dealt with in the paper are the most difficult and unsatisfactory. Pitot tubes, Bentzel tubes, and small current meters all have their shortcomings particularly in exceptionally turbulent flow similar to that encountered in a stilling-basin. Sometimes it is possible to obtain relative values, but in some cases it is practically impossible to obtain velocity measurements that have any value whatever. New instruments based on different principles are needed for these measurements.

---

[8] "Hydraulic Laboratory Projects of the Corps of Engineers, U. S. Army," by F. H. Falkner, Jun. Am. Soc. C. E., *Transactions*, A. S. M. E., Vol. 58, No. 7, p. 561.

Entrained air, referred to in the paper, is not only a factor in scale conversions, but often becomes a source of trouble in piezometer and Pitot tube connections. These connections, from orifice opening to manometer, should be as short as possible. In addition to avoiding sharp bends, they should slope upward throughout their length to eliminate sags where air often becomes entrapped. Mechanical devices for drawing the air out of connections are desirable if not essential. Vacuum pumps or air ejectors are most satisfactory for this purpose.

Capacity of Prototype and Model.—The authors mention the impossibility of reproducing the frictional factor to scale in models of the size of those discussed. They suggest measuring the value of n experimentally and then using it to determine the discharge conversion factor. In a model in which the roughness is significant, this method must be used with caution because the corresponding stages may be considerably in error and the location of the hydraulic jump affected accordingly. For example, consider a model that has too great a value for n. For normal head-water elevation, the conduit discharge would be too small. Under this circumstance a tail-water elevation in the model corresponding to the correct prototype discharge would cause the hydraulic jump to form up stream from its correct position. Particularly in a basin having warped sides and sloping floor, this condition would be difficult to analyze. However, by varying the tail-water elevation for a given discharge, sufficient data may be collected to permit proper analysis of the basin action when the head-water elevation, conduit discharge, and tail-water elevation are correlated.

One solution for the problem arising from the inability to reduce the friction factor below a certain limit is to use a model that is large enough to eliminate the scale effect. This often would require space and discharge capacity beyond the laboratory facilities.

Another solution, which would eliminate the conduit section and provide for studying the intake and stilling-basin in separate models, should be considered for each specific problem. The friction loss in the conduit section would be left entirely to computation.

T. T. KNAPPEN,[9] M. AM. SOC. C. E. (by letter).—The general plan for the Muskingum project, referred to by the authors as the "Official Plan", was prepared by the U. S. Engineer Office, at Zanesville, Ohio, in co-operation with the Muskingum Watershed Conservancy District and was completed about August, 1934. This project then was constructed by the U. S. Engineer Department under the co-operative agreement between the Muskingum Watershed Conservancy District and the U. S. Engineers, representing the Public Works Administration. Since the work was to be constructed with P.W.A. funds and since the law at that time required that all funds be obligated by July 1, 1935, the Designing Staff was faced with the problem of completing the plans and specifications for the entire project by the following May, in order to allow a sufficient period for advertising the work and awarding the contracts. In analyzing the design, it was apparent that numerous difficult hydraulic problems would develop and that the time for their solution would be limited. Negotiations were started, therefore, early in the summer of 1934 with the object of devising an arrangement for testing the proposed hydraulic designs in a suitably equipped hydraulic laboratory. An agreement was finally made with Professor Barnes to have this work done at the Case School of Applied Science, in Cleveland, Ohio, and Mr. Jobes was assigned as representative of the U. S. Engineer Office to assist Professor Barnes in performing the experiments and to serve as a "contact man" between the two organizations.

---

[9] Associate, Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

At the time that these negotiations were going forward, a section was being organized in the Zanesville Office to design the hydraulic structures. Mr. Paul H. Jaenichen was placed in charge of this section. The preliminary hydraulic designs were developed under his direction, and laboratory tests were then run to check and improve the tentative plans. A close relation was maintained at all times between the design section and the laboratory. The hydraulic model experiments were considered as being a part of the actual design. Throughout the course of the experiments, this policy was strictly maintained. Under ordinary circumstances one might have been warranted in conducting these experiments to extend the range of test data beyond the immediate needs of a specific design problem and to obtain information of more general applicability; but the severe time limitation made it necessary to dismantle each model and replace it with another one as soon as the particular problem was sufficiently clarified. Exceptions were made in cases where existing models could be used with little or no alteration for preliminary investigations of similar features on other dams in the project.

Table 1, showing the cost of labor and materials involved in the model testing, is known to be accurate, as a strict system of accounting was established as a basis of approving bills for the work. The over-head charges of 40% are reasonably representative of the actual over-head costs. The total cost of the hydraulic model work, including over-head, was approximately \$42 000, or an average cost of about \$4 000 per model. The construction cost of the fourteen reservoirs of the Muskingum project was approximately \$23 000 000, so that the cost of the hydraulic model testing was slightly less than 0.2% of the project cost. Although hydraulic experiments were made for only eleven of the dams, the results were used on all fourteen. The writer feels that the expenditure was more than justified by the results obtained.

At the beginning of the hydraulic design work, little information was available about hydraulic-jump action in sloping and flaring channels. Considerable difficulties were encountered in the first designs, and many changes were necessary in the first models, in order to arrive at a good stilling-basin arrangement; but as the hydraulic experimental work progressed and test results from the first models were analyzed, definite design rules were developed and the art of designing stilling-basins was gradually mastered. Two models of the outlet structure of the Wills Creek twin conduit were built before a satisfactory solution was found; but the largest part of this cost should be distributed among the other dams, since all the later designs benefited by these first experiments. The designs of the Mohawk and Bolivar outlet works, also twin-conduit structures, gave such surprisingly good check results during the model tests that it was found unnecessary to perform experiments on the Beach City structure, which is in principle the same as the Wills Creek layout. The cost of the Mohawk tests was relatively high, due to the completeness with which the intake structure and the conduit system were reproduced in the model.

The experience with the small single-conduit outlets was similar to that with the large twin-conduit structures. The Tappen and Clendening outlets were treated very completely in the experimental work, and numerous changes were made in these models. The stilling-basin designs for Piedmont and Pleasant Hill were based on these experimental findings, and when tested in the models gave such close check on the original designs that it was felt that the Leesville and Atwood structures could safely be eliminated from the experimental program. The relatively high cost figures for the hydraulic experimental work for the Charles Mill, Dover, Mohicanville, and Pleasant Hill structures are due to the fact that the spillways were included in these models and that the design problems were of an intricate nature.

The use of the hump in the stilling-basin apron at the ends of the tunnels for Tappan, Clendening, and Piedmont, first developed by Mr. R. G. Schneider while assisting in the design of these structures, proved to be an interesting feature. In these cases the conditions for tunnel driving were most favorable at the elevations selected. At Tappan, for instance, if the tunnel had been raised to the required invert elevation to avoid the use of the hump, the crown would have broken through a hard sandstone into soft shale which would have required timbering the tunnel at an increased cost of about $10 000.

It is worthy of note, that the hydraulic jump at Clendening is created by the hump in the stilling-basin apron; without it, unsatisfactory stilling performance would have to be expected under the prevailing conditions of high tail-water. In the case of the work at Tappan, plans and specifications were issued, and the construction was started in advance of the completion of the hydraulic experiments. Because of this, it was not feasible to make all the modifications indicated by these studies. The model experiments showed that an eddy could be expected in the stilling-basin under certain conditions of discharge and tail-water, because of the unnecessary basin width, whereas under more favorable conditions this eddy would not occur. The writer was fortunate enough to see both these conditions reproduced in the prototype in the spring of 1936, after having witnessed the condition in the model. A very close agreement between behavior of model and actual structure was observed.

During the 1937 flood, the Muskingum Conservancy District was unable, because of legal difficulties, to close any of the gates for regulation, so that even with considerable outflows, discharge heads were relatively small and tail-water levels were higher than normal, due to the small controlling effect of the reservoirs. Thus, stilling-basins during this flood were subject to an extreme and very unusual test. In all cases observed, the hydraulic jump developed very close to the exit portal. The condition of outflow with low kinetic energy and high tail-water is difficult of proper treatment in the design, due to the proximity of unbalanced hydraulic-jump conditions, but the structures acted remarkably well under this test. In comparison with the hydraulic model work, it may be stated herein that the appearance of the stilling performance in the actual structures was far better than that found under similar conditions in the model tests. Various small and rather unimportant flow details that had been observed on the models were reproduced in the actual structures in striking similarity.

An interesting point developed by the model tests was that the flare of the side-walls and the width of the stilling-basin should be limited to obtain the best hydraulic-jump action. This was borne out by a comparison of the action of the Wills Creek and Mohawk Dams during the 1937 flood (Figs. 11 and 12). In their general layout these outlet structures have much in common, both having large twin conduits. The length of the Wills Creek Basin was limited by the dropping off of the rock formation under the far end of the right-basin wall. Its sloping apron is slightly too steep, and the basin width required to reduce the exit velocity to safe limits is somewhat too large for proper jump action. Fig. 11 shows the Wills Creek Dam discharging about 15 000 cu ft per sec, or 7 500 cu ft per sec from each conduit, during the January, 1937, flood. The back rolls along each side-wall, induced by the departure from ideal conditions described previously, are plainly visible. Fig. 12 shows the Mohawk Dam during the same flood, discharging about 16 000 cu ft per sec under similar tail-water conditions. The attainment of close to an ideal design is indicated by the absence of back rolls.

The writer would like to emphasize the effect of baffle-blocks as described by the authors. The model studies showed repeatedly that properly located baffle-blocks stabilize the jump action, permit the use of somewhat shorter stilling-basins, and provide a factor of safety against unforeseen low tail-water conditions.

A controlling influence in the design of outlet structures is the correct determination of the tail-water conditions. The writer was impressed, by the Muskingum model studies, with the importance of securing accurate survey data from which to compute rating curves below dam sites.

The authors are to be congratulated on presenting this excellent paper, and particularly for setting forth cost data and describing in considerable detail the method of model construction. As they suggest, the cost data must be used with caution, as they are representative of a project involving a large number of structures. Had the model works not been grouped in a continuous program, the costs would have been probably 25% to 50% greater. The writer feels that the expenditure was more than justified

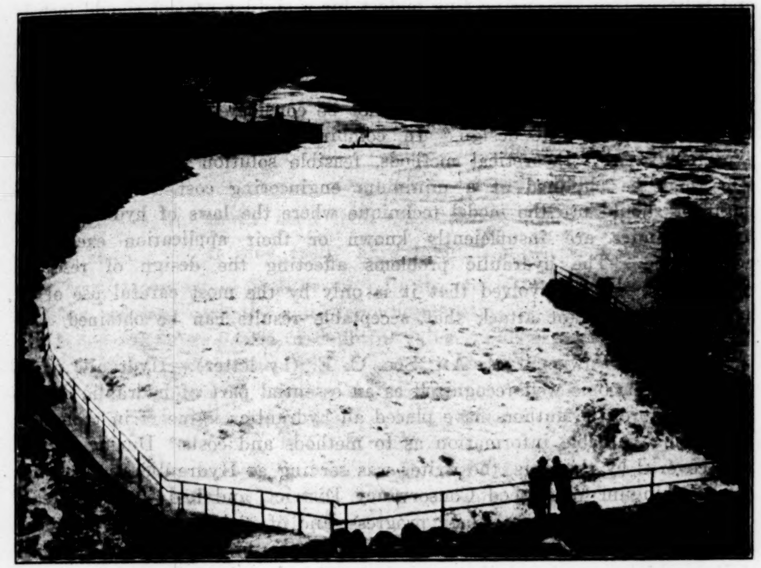

FIG. 11.—WILLS CREEK DAM, OHIO, 1937: STILLING-BASIN FROM TOP OF DAM (DISCHARGE, 15 000 CUBIC FEET PER SECOND)

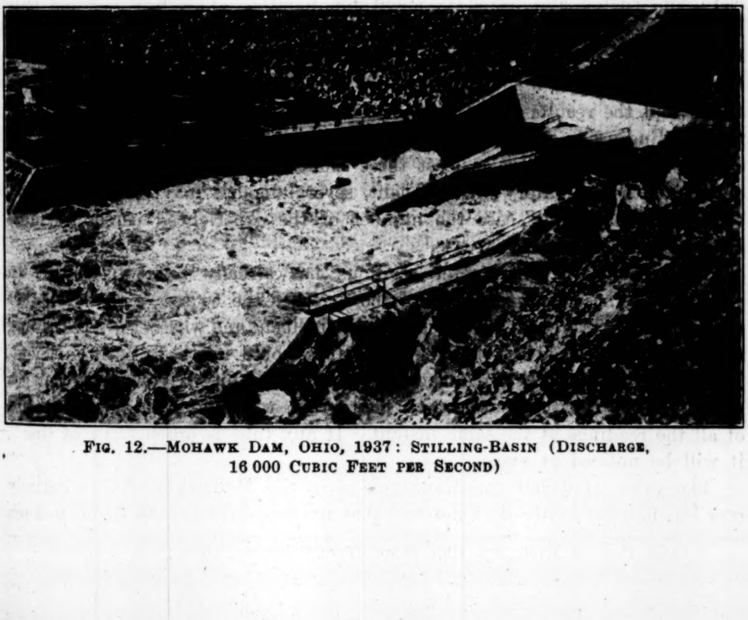

FIG. 12.—MOHAWK DAM, OHIO, 1937: STILLING-BASIN (DISCHARGE, 16 000 CUBIC FEET PER SECOND)

and believes that the engineering budget for a similar project should include an allowance for model tests as a part of the necessary and warranted design cost.

The writer concludes from his experience on the Muskingum project that model tests of this type should not be considered as a full substitute for careful analytical design. In combining, properly, hydraulic model experiments with theoretical methods, feasible solution of hydraulic problems may be obtained at a minimum engineering cost. The hydraulic engineer should use the model technique where the laws of hydraulics and hydrodynamics are insufficiently known or their application excessively complicated. The hydraulic problems affecting the design of reservoir outlet work are so involved that it is only by the most careful use of all available methods of attack that acceptable results can be obtained.

RALPH W. POWELL,[10] M. AM. SOC. C. E. (by letter).—Hydraulic model testing has become well recognized as an essential part of hydraulic design, and, therefore, the authors have placed all hydraulic engineers in their debt by sharing valuable information as to methods and costs. During the period covered by the tests, the writer was serving as Hydraulic Engineer for the Muskingum Watershed Conservancy District, and had the pleasure of observing several of the tests in progress, and of making a fairly thorough study of the complete reports which were prepared. This contact gave the writer a high regard for what was accomplished under very definite limitations.

As far as the writer is aware, no equal amount of model testing has ever been done in one laboratory in an equal length of time. Thirteen models were constructed and tested in about ten months. This was possible only by working the models on three 8-hr shifts, and meant 13 or 14-hr days for the Supervisory Staff. Although the authors are to be congratulated on the work done under such conditions, they would probably be the first to admit that the results might have been better if more time could have been taken. Engineers who wish model tests comparable to those described should, if possible, allow at least three months for each model. If the facilities of the laboratory are sufficient, several models may be tested simultaneously, but in this case the number of the experienced personnel must be increased accordingly.

The problem of piezometer readings has already been discussed. In view of the uncertainty of many of the readings the writer wonders whether the hook-gages were not an unnecessary refinement and whether direct reading manometers arranged in "gangs" on boards would not have been sufficient. This arrangement has the advantage that the prototype elevations can be marked plainly on the board, and a photograph will give a permanent record of all the readings at the same instant. If any tube is much "out of line", it will be noticed at once.

The value of 0.0091 for Manning's n in the Mohawk model is entirely possible, but the writer does not feel that much weight can be given to such measurements. Prandtl and Tietjens[11] state that in the case of turbulent flow, the kinetic energy head increases from $\frac{V^2}{2g}$ to $1.09\,\frac{V^2}{2g}$ in the first 40 diameters of the length of the pipe. In a complicated structure like the outlet works of the Mohawk Dam, it is somewhat of a question what point to consider as the entrance, but using the gate slots, the points at which the pressure was measured were approximately 11 and 21 tunnel diameters down stream from the entrance, respectively. How much of the $0.09\,\frac{V^2}{2g}$ increase in kinetic energy head took place between these two sections is difficult to say, but it may easily have been as much as $0.02\,\frac{V^2}{2g}$. This would be of the order of 10% or more of the entire pressure drop observed. This fact, coupled with the admitted uncertainties in the piezometer readings, makes the figure 0.0091 of doubtful value. This is entirely apart from the doubt which grows constantly in the writer's mind as to whether Manning's formula should be used in model work at all. A better means of expressing fluid friction in conduits is badly needed.

George E. Barnes,[12] M. Am. Soc. C. E., and J. G. Jobes,[13] Jun. Am. Soc. C. E. (by letter).—The discussion shows corollary experience in other laboratories, with the inherent difficulty of securing desired precision in piezometer and velocity readings. The value of model studies, now established beyond question, will be much enhanced, of course, by any improvements in laboratory technique.

Messrs. Howard and Edwards both submit practical suggestions on the piezometer connections, piezometer tubing, and indicating devices. With these, and with Mr. Edwards' comments on velocity meters, the writers concur. In the laboratory at Case School of Applied Science, hook-gage buckets for gangs of piezometers have been found less practical, in most cases, than a bank of piezometer-indicating tubes joined at the top by a header, and connected to pressure and suction lines by suitable valves. It all depends, however, upon the precision and convenience desired, and no generalization is offered.

As the writers stated, too much confidence is not warranted in the experimental values of n determined for these short model tunnels. Professor Powell amplifies this observation by reference to the probable influence of the intake structure on velocity distribution. In a thesis study,[14] it was demonstrated conclusively that the apparent value of n in the model tunnel of Pleasant Hill Dam could be changed by baffling the entrance in a manner that would influence velocity distribution. Furthermore, the measurements indicated that the value of n may change with the rate of discharge; and, as implied by Mr. Edwards, a value of n which is on the safe side for the capacity of the tunnels, is on the unsafe side for the performance of the stilling-basin. It is necessary to determine the value of n in order to calibrate the delivery capacity of the outlet works. In operating the stilling-basin, however, it is the quantity of discharge that is important. For a given discharge, excess head may be needed.

All observers agree that the design must provide for probable deviations in tail-water level from those predicted. The extent of this deviation is a matter of judgment based on the probable strength of the data from which the tail-water rating curve is derived.

Mr. Knappen's discussion is most generous in scope. As the then Chief of the Engineering Division of the U. S. Engineer Office, at Zanesville, Ohio, his viewpoint is most valuable. Perhaps too much weight is given the dollars and cents savings made possible by model studies and too little weight is given the fact that such studies, in many cases, are worth while simply as a guaranty of good performance. Certainly, the art of stilling-basin design alone was greatly advanced in this work, and as Mr. Knappen indicates, it became more and more possible to be right the first time as the studies progressed. This was despite the wide variety of designs for the several dams.

The design of the Clendening Dam, discussed by Mr. Knappen, was mentioned by the writers as an interesting departure from orthodox design. It also illustrates how an idea for design will germinate during the manipulation of a model. In previous and incompleted tests on Tappan Dam, stilling-basin performance with the tunnel at various elevations was studied for low discharges by merely inserting filler pieces or "humps" on the floor of the tunnel portal, as described. This was quicker and more convenient than continually changing the model around and, in a rough and tentative manner, it gave the approximate effect of raising or lowering the tunnel. Here was born the idea of a low tunnel, with a portal or apron of greater lateral width and high invert, although a simpler design was preferred if field conditions would permit raising the tunnel throughout its length. However, the so-called "hump" proved well adapted to field conditions at Tappan, Clendening, and Piedmont Dams, and the first design for Clendening was so drawn up, although some changes were made after test.

Professor Powell dwells on the expedition with which the work was handled, and the limitations which this imposed on the scope of the tests. Expedition marked the handling of the Muskingum Water-Shed Project as a whole, and was, in fact, a condition precedent to the approval of the project. It might be stated, therefore, that the model studies would have failed in their purpose, had each individual study been extended beyond the time allowed. Unquestionably, this program limited the findings secured.

The writers did not intend to elaborate upon technical findings and design, but rather on matters affecting the programming of model studies. The following remarks are offered in closure: As part of the design procedure, model studies for a given project may be simple or elaborate depending on objectives. These objectives may be limited to taking observations on matters of only immediate or primary concern in the design, or they may be extended in detail or expanded to general research to facilitate the planning of a series of integrated developments with other projects in view. Model studies ordinarily should start with preliminary studies and should be carried along concurrently with design. The writers believe it undesirable to issue contract drawings for bidding purposes before the model studies are completed, on the assumption that changes will be minor in character, since under these circumstances they are likely to be in the nature of a compromise and the design does not receive the full benefit of the model studies. In the case of the Muskingum Water-Shed Project, model studies commenced at the very beginnings of design, which is the best possible arrangement, and most productive for all concerned.

Paper No. 1986

ANALYSIS OF STRESSES IN SUBAQUEOUS TUNNEL TUBES

By A. A. Eremin,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. David J. Peery, Orrin L. Brodie, and A. A. Eremin.

Synopsis

Stresses in a concrete tunnel tube with flexible horizontal ties, are analyzed in this paper. The equations for computing stresses in the tube and ties are based on the Maxwell theorem of reciprocal displacements. Stresses in a tube may also be determined by the Method of Least Work, although the resulting equations are lengthy and require considerable computation. The dimensions of a tube and its tie-rods are generally proportioned by trial and error and, therefore, it is essential to save time in the analysis of the stresses. Changes in the dimensions of the tube and ties require the computation of fewer terms in the equations based on the Maxwell theorem than in the Method of Least Work.

Introduction

The elastic tube lining with flexible horizontal ties has found wide application in the construction of subaqueous tunnels. In Fig. 1, for example, the roadway is placed at the center of the section. The upper horizontal ties are enclosed in the ceiling slab, the space above being used for an exhaust ventilating duct. The lower horizontal ties are placed in the roadway slab, the space beneath it being occupied by the fresh-air ventilating duct. These rods cause a more even distribution of the stresses in the ring.

The tunnel lining may be either a reinforced concrete tube or a series of cast-iron rings bolted at the flanges. Each type has been found advantageous from a construction or economic standpoint, depending on the site and the soil to be penetrated. In the Posey Tube under the estuary channel between Oakland and Alameda, Calif., reinforced concrete pre-cast sections were used.

Note.—Published in December, 1936, *Proceedings*.

[1] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

In this case the horizontal steel tie-rods were placed in the ceiling, the roadway slab being designed to act as a strut to resist external soil pressure.[2] In the Holland Vehicular Tunnel under the Hudson River between New Jersey and New York, the tube was made of bolted cast-iron rings. The high tensile steel tie-rods were placed in the ceiling and roadway slabs.[3]

FIG. 2.—DIAGRAM OF BASIC TUBE.

The equations developed in this paper refer to the analysis of stress in a reinforced concrete tube. However, they may also be used for the analysis of stresses in a cast-iron tube by substituting the proper values for the modulus of elasticity. The basic assumptions made for the elastic materials generally used in the theory of elasticity were adopted for this paper. However, the possible effect of plastic flow in concrete was not considered.

Notation.—The letter symbols in this paper are introduced in the text as they occur and are summarized for reference in the Appendix. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials"[4] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

DERIVATIONS

The loading sustained by a tunnel tube consists of external earth and water loads, the weight of the structure, the live loads on the roadway deck, and the force of buoyancy. The ring and the loads acting on it are generally symmetrical about a vertical axis through the crown section, and, consequently, the stresses involved are also symmetrical about the vertical axis. The shearing stresses at the upper and lower crown sections are equal to zero. In developing the equations the half-ring shown in Fig. 2 is analyzed, representing a 1-ft length of tube, fixed at the bottom, with the right half removed. The tie-rods are replaced by tensile forces, and the reactions from the right half are expressed by the horizontal force and bending moment applied at the elastic center of the tube.

An elastic tube with two horizontal flexible tie-rods is statically indeterminate in the fourth degree; that is, there is a deficiency of four equations for solution as a statically determinate problem. The following are the conditions to be met: (1) From symmetry, the vertical diameter in Fig. 2 may be assumed as fixed; (2) the horizontal displacement and the rotation of the crown sections may be equated to zero; and (3) the horizontal displacements of the ring, at the points where the tie-rods are connected are equal to the strains in the corresponding ties.

[3] *Loc. cit.*, December 3, 1925, p. 902.
[4] A.S.A.—*Z10a*—1932.

Case 1.—Tunnel Section Without Tie-Rods.—Equations developed for determining stresses in an elastic rib arch fixed at the ends,[5] may be adapted to the solution of stresses in any closed ring without tie-rods. Since such a ring is symmetrical about the vertical axis, its elastic center will be on the vertical axis and its distance from the upper crown section, y_c, may be computed from the equation,

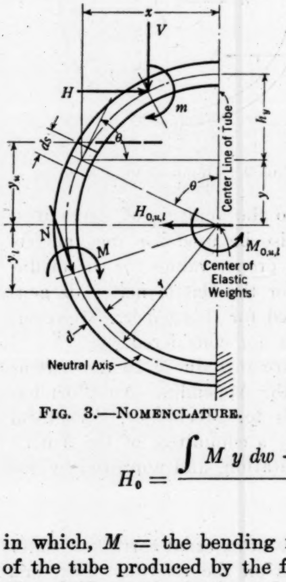

FIG. 3.—NOMENCLATURE.

$$y_c = \frac{\int h_y\, dw}{\int dw} \quad \ldots\ldots\ldots\ldots (1)$$

in which (see Fig. 3), h_y = the vertical distance from the axis at the crown, to any point, x, y, on the ring; $dw = \frac{ds}{E_c I}$, the elastic weight of the arch element; ds = the length of an element measured along the neutral axis; E_c = the modulus of elasticity of the concrete in compression; and I = the moment of inertia of the section of the tube.

The horizontal force, H_0, that expresses the effect of the right-half ring (transmitted through the hypothetical arm shown in Fig. 2) is determined from:

$$H_0 = \frac{\int M\, y\, dw + \int H \cos^2\theta\, dv + \int V \sin\theta \cos\theta\, dv}{\int y^2\, dw + \int \cos^2\theta\, dv} \quad \ldots\ldots (2)$$

in which, M = the bending moment at some point, x, y, on the neutral axis of the tube produced by the forces applied between that point and the crown; H and V are the horizontal and vertical components of the sum of all the forces between Point x, y, and the crown; $dv = \frac{ds}{E_c A}$; A = the area of the section cut by a radial plane, per linear foot of tunnel; and θ = the angular distance of Point x, y, measured counter-clockwise. The moment, M_0, at the elastic center, introduced to allow for the removal of one-half the tunnel tube, is:

$$M_0 = \frac{\int M\, dw}{\int dw} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

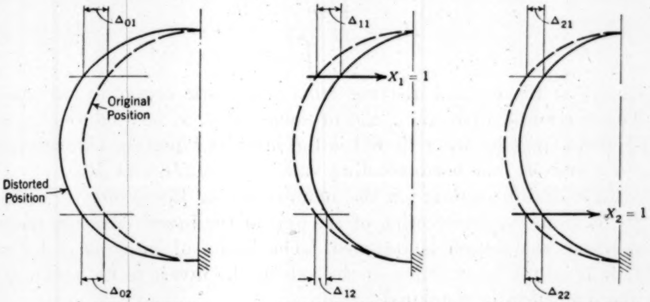
---

[5] "Movable and Long-Span Steel Bridges", by G. A. Hool and W. S. Kinne, p. 440.

The horizontal distortion at Point x, y, (see Fig. 4) may be determined by:

$$\Delta_{0u} = \int M\, y\, dw + \int H \cos^2 \theta\, dv + \int V \sin \theta \cos \theta\, dv$$
$$- H_0 \left(\int y^2\, dw + \int \cos^2 \theta\, dv \right) - M_0 \int y\, dw \; \ldots \ldots \ldots \ldots (4)$$

the integration being taken from the fixed support to Point x, y. When the external load is a unit horizontal force applied at the upper tie-rod joint (Fig. 4(*b*)), the horizontal and vertical components are $H = 1$, and $V = 0$,



(*a*) DUE TO EXTERNAL LOADING (*b*) DUE TO UNIT FORCE AT UPPER TIE ROD (*c*) DUE TO UNIT FORCE AT LOWER TIE ROD

FIG. 4.—DIAGRAMS OF HORIZONTAL DISTORTION.

and the bending moment at Point x, y (Fig. 3), on the neutral axis below the upper tie-rod joint is,

$$M = y_u - y \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots (5)$$

in which, y_u = the vertical distance of the upper tie-rod joint from the elastic center. Therefore, from Equation (2), the horizontal reaction at the elastic center, produced by a unit force at the upper tie-rod joint is:

$$H_u = \frac{\int y\,(y_u - y)\, dw + \int \cos^2 \theta\, dv}{\int y^2\, dw + \int \cos^2 \theta\, dv} \ldots \ldots \ldots \ldots (6)$$

and the reaction bending moment, from Equation (3) is,

$$M_u = \frac{\int (y_u - y)\, dw}{\int dw} \ldots \ldots \ldots \ldots \ldots \ldots (7)$$

From Equation (5) the horizontal distortion at some point, x, y, on the neutral axis, produced by a unit force acting along the upper tie-rod is:

$$\Delta_{1u} = \int y\,(y_u - y)\, dw + \int \cos^2 \theta\, dv$$
$$- H_u \left(\int y^2\, dw + \int \cos^2 \theta\, dv \right) - M_u \int y\, dw \ldots \ldots \ldots (8)$$

Likewise, the horizontal thrust, H_l, and the bending moment, M_l, at the elastic center of the ring produced by a unit force applied along the lower tie-rod, are:

$$H_l = \frac{\int y\,(y_l - y)\,dw + \int \cos^2\theta\,dv}{\int y^2\,dw + \int \cos^2\theta\,dv} \quad \dots\dots\dots\dots\dots (9)$$

and,

$$M_l = \frac{\int (y_l - y)\,dw}{\int dw} \quad \dots\dots\dots\dots\dots\dots\dots (10)$$

in which, y_l = the vertical distance from the elastic center to the lower tie-rod. The horizontal distortion, Δ_{1l}, of some point, x, y, produced by a unit force applied along the lower tie-rod is the same as Equation (8), substituting for y_u, H_u, and M_u, the corresponding values of y_l, H_l, and M_l.

The limit of integration for the nominators in Equations (6), (7), (9), and (10), is from the intersection of the axis at the invert crown to the point, x, y, at which the tie-rod is fastened. The limits of integration for Equation (8) is from the intersection of the axis at the invert to the point, x, y, at which the distortion is computed.

Case 2.—Tunnel Section with Horizontal Tie-Rods.—Whereas, a circular, elastic tube with two horizontal tie-rods is statically indeterminate in the fourth degree, without the tie-rods the section is statically indeterminate in the second degree, and in the latter case, the reaction forces may be computed by Equations (2) and (3). Stresses in the tie-rods may be determined from the Maxwell theorem of reciprocal displacements.

The horizontal distortions at the level of the upper and lower tie-rods are, respectively, Δ_{ou} and Δ_{ol}. In the tube with ties these distortions are corrected by tensile forces in the tie-rods. The final force in the upper tie-rod, assisting the tube to carry the external loads, is indicated by X_u and at the lower rod by X_l. The horizontal distortion at the upper tie-rod joint produced by the upper tie-rod stress is $X_u \Delta_{1u}$, and the distortion produced by the lower tie-rod stress is $X_l\,\Delta_{1l}$. The total distortion of the ring at the level of the upper tie-rod, from its original position, is equal to one-half the strain in that tie-rod, or

$$\Delta_1 = \frac{X_u\,L_u}{2\,E_s\,A_u} \quad \dots\dots\dots\dots\dots\dots\dots\dots (11)$$

(assuming no initial tension in the tie-rod). Therefore, from the Maxwell theorem the equation may be written:

$$\frac{X_u\,L_u}{2\,E_s\,A_u} = X_u\,\Delta_{1u} + X_l\,\Delta_{1l} + \Delta_{ou} \quad \dots\dots\dots\dots\dots (12)$$

Likewise, for the lower tie-rod an equation of distortion may be written:

$$\frac{X_l\,L_l}{2\,E_s\,A_l} = X_l\,\Delta_{2l} + X_u\,\Delta_{2u} + \Delta_{ol} \quad \dots\dots\dots\dots\dots (13)$$

in which, A_u and A_l are the sectional areas of the upper and lower tie-rods, respectively. From Maxwell's theorem $\Delta_{1l} = \Delta_{2u}$. Solving, simultaneously, Equations (12) and (13) the reactions, X_u and X_l, in the tie-rods may be determined.

The horizontal thrust, H_c, and the bending moment, M_c, at the elastic center of the tube, with tie-rods, may be computed from:

$$H_c = H_0 + X_u H_u + X_l H_l \text{ ....} (14)$$

and,

$$M_c = M_0 + X_u M_u + X_l M_l \text{ ....} (15)$$

The bending moment, M, and the normal thrust, N, at any radial section may be computed from statics; thus, for points on the axis of the ring between the upper tie-rod and the horizontal diameter of tube:

$$M_q = - M_c + H_c\, y + M + X_u\, (y_u - y) \text{ ....} (16)$$

and,

$$N = H_0 \cos\theta - H \cos\theta + V \sin\theta - X_u \cos\theta \text{ ....} (17)$$

Case 3.—Temperature Stresses.—Assuming the tie-rod removed, the horizontal thrust at the elastic center, produced by a change (t) in the temperature of the atmosphere is expressed by:

$$H_t = \frac{c\, t\, r\, E_c}{\int y^2\, dw + \int \cos^2\theta\, dv} \text{ ....} (18)$$

in which, c = a coefficient of temperature expansion or contraction of concrete for 1° variation in temperature; and r = the radius of the neutral axis of the tube.

The horizontal distortion of some point, x, y, on the neutral axis of the tube for a change of temperature of $t°$ is expressed by:

$$\Delta_t = c\, t\, r\, E_c - H_t \left(\int y^2\, dw + \int \cos^2\theta\, dv \right) \text{ ....} (19)$$

Tension or slack in the upper and lower tie-rods produced by temperature changes in the atmosphere may be computed from Equations (12) and (13), except that Δ_{01} and Δ_{02} must be changed to the temperature distortions, Δ_{tu} and Δ_{tl}, in the upper and lower rods. Temperature stresses may be computed also for differences in temperature between rods and ring, with appropriate distortions, Δ_{tu} and Δ_{tl}. It should be noted that the earth pressure loads may also change with changes in temperature.

Case 4.—Circular Tunnel Tube of Uniform Thickness.—The equations for computing stresses in a circular ring of uniform thickness may be simplified considerably. The elastic center of the tube will be in the geometric center of the ring. The co-ordinates of a radial section may be expressed by angular functions, thus,

$$x = r \sin \theta \quad \text{.........................} \quad (20)$$

$$y = r \cos \theta \quad \text{.........................} \quad (21)$$

$$ds = r \; d\theta \quad \text{.........................} \quad (22)$$

$$dw = K_1 \; r \; d\theta \quad \text{.........................} \quad (23)$$

and,

$$dv = K_2 \; r \; d\theta \quad \text{.........................} \quad (24)$$

in which, $K_1 = \dfrac{1}{E_c \, I}$; and, $K_2 = \dfrac{1}{E_c A}$. Substituting Equations (20) to (24) in Equations (2), (3), and (4):

$$H_0 = \frac{r \; K_1 \int M \cos \theta \; d\theta + K_2 \int H \cos^2 \theta \; d\theta + K_2 \int V \sin \theta \cos \theta \; d\theta}{(r^2 \, K_1 + K_2) \int \cos^2 \theta \; d\theta} \quad \text{....} \quad (25)$$

$$M_0 = \frac{\int M \; d\theta}{\int d\theta} \quad \text{.........................} \quad (26)$$

and,

$$\Delta_0 = r \, K_1 \int M \cos \theta \; d\theta + K_2 \int H \cos^2 \theta \; d\theta + K_2 \int V \sin \theta \cos \theta \; d\theta$$

$$- \; (K_1 \, r^2 + K_2) \int \cos^2 \theta \; d\theta - r \, K_1 \, M_0 \int \cos \theta \; d\theta \quad \text{.........} \quad (27)$$

EXAMPLE 1

As an illustration of the practical application of the equations developed, the stresses in the elastic tunnel tube with the tie-rods in the ceiling were computed. Fig. 5 shows the dimensions of the tube and the external loads acting on it. In addition, the sectional area of the tie-rods is $A_u = 1.3$ sq in. per lin ft of tunnel; the length of the tie-rods is $L_u = 29.67$ ft; and the vertical distance to the tie-rod from the center of the tube is $y_u = 8.80$ ft.

5800 Lb per Sq Ft

FIG. 5.—TUBE SECTION AND LOADING USED IN EXAMPLE.

From symmetry it follows that the elastic center of the tube corresponds to the geometric center of the ring. The horizontal thrust, H_0, and the bending moment, M_0, produced by the external loading, as computed by Equations (25) and (26), are $H_0 = 81\,500$ lb and $M_0 = 1\,450\,000$ ft-lb. The horizontal distortion, Δ_{01}, at the point, y_u, (with the tie-rods removed), due to the external loading, is computed by Equation (27): $\Delta_{0u} = 0.248$ ft. The horizontal thrust, H_u, and bending moment, M_u, at the elastic center produced by a horizontal load of 1 000 lb at the point, y_u, as computed by Equations (6) and (7) are: $H_u = 668$ lb, and $M_u = 10\,600$ ft-lb. The horizontal distortion of the tie-rod joint of the tube produced by a horizontal force of 1 000 lb at y_u, as computed by Equation (8) is, $\Delta_{1u} = 0.011$ ft. The strain in the tie-rod produced by a tensile force of 1 000 lb, is: $\Delta_u = \dfrac{1\,000 \times L_u}{2\,E_s\,A_u} = 0.00038$ ft.

Substituting the values of the distortions in Equation (12) and solving, the unknown reaction in the tie-rods is found to be $X_u = 22\,877$ lb. In Equation (12), for the present example, $X_l = 0$. The unit stress in the tie-rods is: $f_s = \dfrac{X_u}{A_u} = \dfrac{22\,877}{1.3} = 17\,598$ lb per sq in. The effect of the direct stresses on the reactions at the elastic center and the horizontal distortions of the tube have not been considered in this example.

SUMMARY

The advantages of the equations based on the Maxwell theorem in computing the stresses in a tunnel tube may be summarized, as follows:

(1) The stresses in the shell and tie-rods of a tunnel may be computed by an adaptation of Maxwell's theorem with the same precision as by any other refined method based on the theorem of least work.

(2) The significance of the various terms in the equations for computing the stresses may easily be visualized. Therefore, the computation of stresses may be simplified by reducing them for negligibly small terms. Furthermore, the simplicity of interpreting the signs of the expressions for distortion at tie-rods is self-evident.

(3) The "trial-and-error" changes in the dimensions of a tunnel tube and the tie-rods in the method based on Maxwell's theorem will affect a smaller number of the terms than is the case with the method of least work.

(4) Further simplifications may be introduced by preparing tables and diagrams for the geometrical constants involved.

(5) The method of computing stresses in the tube based on Maxwell's theorem has a wide application. It may readily be used in computing stresses in any other type of statically indeterminate structures.

The necessity for a shorter and more accurate method of computing stresses in a tunnel tube is unquestionable. In this respect, the method presented herein, based on Maxwell's theorem, will be of interest to the designers of tunnels.

APPENDIX

NOTATION

The following symbols, defined where first introduced in the paper, are re-arranged herein for convenience of reference:

A = area of a radial section of a 1-ft length of tunnel; also, with subscripts, A = cross-sectional area of a tie-rod per linear foot of tunnel, A_u referring to the upper of two rods, and A_l to the lower rod;

c = coefficient of expansion or contraction of concrete for a change in atmosphere of 1° F;

d = thickness of the tunnel ring;

E = modulus of elasticity: E_c, for concrete in compression; and E_s, for steel in tension;

f = unit stress, f_s, referring to unit steel stress;

H = horizontal thrust or reaction; horizontal component of force at any point, x, y, produced by forces on the ring between that point and the crown; H_c = horizontal component of force at the crown section, transferred to the center of the elastic weights; H_0 = horizontal component of force applied at the center of the elastic weights to allow for the removal of one-half the tunnel section; H_u = a horizontal force at the center of the elastic weights produced by a unit force applied along the upper tie-rod; H_l = a horizontal force at the center of the elastic weights, applied along the lower tie-rod; H_t = a horizontal thrust at the center of the elastic weights, produced by a change, t, in the temperature of the atmosphere;

h = height; h_y = the vertical distance from the crown to any point, x, y, on the axis of the tunnel ring;

I = moment of inertia of a radial section cut from a 1-ft length of tunnel;

K = a constant; $K_1 = \dfrac{1}{E_c\,I}$; and $K_2 = \dfrac{1}{E_c A}$;

L = length of a tie-rod between its intersection with the axis of the tunnel ring, L_u referring to the upper of two rods and L_l to the lower rod;

M = moment; the bending moment at any point, x, y, produced by the forces on the ring between that point and the crown; M_c = moment at the crown, transferred to the center of the elastic weights; M_0 = moment applied at the center of the elastic weights to compensate for the removal of one-half the ring; M_u and M_l = moment at the center of the elastic weights produced by a unit rotation in the tunnel ring at y_u and y_l, respectively; and M_t = moment at the center of the elastic weights produced by a change, t, in the temperature of the atmosphere; M_q = the bending moment at any point of the tunnel tube with tie-rods, Equation (16).

N = component of thrust normal to a radial plane through any point of the tunnel tube;

p = pressure per unit area; on the 1-ft length of tunnel, p_1, p_2, and p_3, = the uniformly distributed loads on the top, bottom, and sides, respectively, of the tunnel ring (see Fig. 5);

r = radius of a circle described from the center of elastic weights; the radius of the geometric center of the neutral axis of a circular tunnel section;

s = linear distance, measured along the axis of a tunnel section; ds = an element of s;

t = change in the temperature of the atmosphere, in degrees Fahrenheit;

V = vertical component of force at any point, x, y, due to forces on the ring between that point and the crown;

dv = elastic weight with normal stress $= \frac{ds}{E_c A}$;

w = weight; dw = elastic weight $= \frac{ds}{E_c\, I}$;

X = a tie-rod force, or reaction, X_u, referring to the upper tie-rod and X_l to the lower one;

x = a horizontal distance measured from the center of elastic weights;

y = a vertical distance measured from the center of elastic weights; y_c = the distance to the neutral axis of the tunnel ring at the crown; y_u = the distance to the upper tie-rod; y_l = the distance to the lower tie-rod;

Δ = horizontal distortion or displacement; Δ_0 = the distortion at any point x, y, due to external loading; Δ_u = the distortion in the tunnel ring, at Point y_u; Δ_1 = the distortion at any point, x, y, due to a unit load applied along the upper tie-rod; Δ_2 = the distortion at any point, x, y, due to a unit load applied along the lower tie-rod; Δ_l = the distortion in the tunnel ring at y_l; Δ_t = distortion at any point, x, y, due to a change in the temperature of the atmosphere; Δ_{01} = the distortion in the tunnel ring at Point y_u due to strain in the upper tie-rod $= \frac{X_u\, L_u}{2\, E_s\, A_u}$; Δ_{02} = the distortion in the tunnel ring at Point y_l due to strain in the lower tie-rod $= \frac{X_l\, L_l}{2\, E_s\, A_l}$;

θ = angular distance; the angle between a horizontal line through any point, x, y, and the tangent to the neutral axis at that point; in a circular tunnel section the angular distance (central angle) to Point x, y, measured counter-clockwise.

DISCUSSION

DAVID J. PEERY,[6] JUN. AM. SOC. C. E. (by letter).—The method described in this paper is quite convenient for purposes of computation and design, being a very simple and ingenious method for analyzing a structure which is statically indeterminate in the fourth degree. Equation (4), however, represents the horizontal deflection of the elastic center, rather than the deflection of a point on the ring. In order to avoid ambiguity in nomenclature, assume that the specific point at which the deflection is desired has the co-ordinates, x', y'. Other nomenclature will be as shown in Fig. 3, the variables, x and y, representing the co-ordinates to the curve of the neutral axis of the ring. The horizontal distortion at Point x', y', will be.

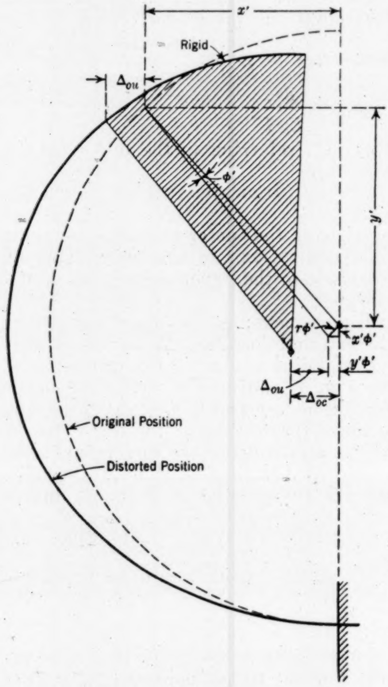

FIG. 6

$$\Delta_{ou} = \int M (y - y')\, dw + \int H \cos^2 \theta\, dv + \int V \sin \theta \cos \theta\, dv - H_0 \left[\int y (y - y')\, dw + \int \cos^2 \theta\, dv \right] - M_0 \int (y - y')\, dw \quad \ldots\ldots\ldots\ldots (28)$$

the limits of integration being taken from the fixed support to Point x', y'. If the limits of integration are taken from the fixed support to the Point x', y', Equation (4) represents the horizontal deflection of the elastic center when the part of the ring between the fixed support and the Point x', y', is considered flexible and the other part of the ring is considered rigid. If this deflection is Δ_{oc}, Equation (4) and Equation (28) yield:

$$\Delta_{ou} = \Delta_{oc} - y' \int (M - H_0\, y - M_0)\, dw \quad \ldots\ldots\ldots\ldots (29)$$

The term under the integral sign represents the angular rotation of the tangent at Point x', y'. Equation (4) will represent the horizontal deflection of Point x', y', only when there is no rotation of the tangent at the point, x', y'. This will not be true in a general case. If this rotation at Point x', y', is called ϕ', Equation (29) becomes:

---

[6] Instructor, Carnegie Inst. of Technology, Pittsburgh, Pa.

$$\Delta_{ou} = \Delta_{oc} - y' \phi' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

The geometric significance of the last term in Equations (29) and (30) is evident from Fig. 6. Equations (8) and (27) of the paper will also have to be adjusted in the same manner.

ORRIN L. BRODIE,[7] M. AM. SOC. C. E. (by letter).—Simplification of analyses for obtaining the most probable stresses to be expected in subaqueous tunnel tubes is always welcome and the author has presented his method of analysis clearly and briefly. His paper should prove serviceable to all engaged in this kind of work.

The application of the Maxwell theorem of reciprocal displacements, while not novel, is extremely apt in connection with the feature of the restraining effect of horizontal tie-rods. Mr. Eremin is correct in his conclusion that the use of this theorem, in this respect, affords a simplification over that of the method of least work; but the writer has applied the latter to tunnel stress analysis, by means of a simple graphic adaptation of the method, which served as a satisfactory check to the more precise method by deflections. The use of the elastic center for the origin is also simpler, in the deflection method, than placing the origin at the invert, as has been done in studies of this kind. Tabular methods of computation always should be used; but after the basis of computation has been established by the theory, it is doubtful whether or not, in general, the subsequent labor of computing varies much. As the author has stated, the mechanical part is a matter of preparing tables and diagrams.

Although it is obvious that the theoretical derivations, such as those outlined in the paper, are independent of the physical conditions surrounding the structure, nevertheless the paper arouses curiosity along the lines of the assumed loadings for the tunnel considered. Some developments of tunnel stress theory have incorporated the "external loading" in the integrations. The author very properly has omitted these, as they only encumber the analysis unnecessarily, especially as the use of unit forces and moments suffices in this respect; but as the main objective of any analysis is to make practical application toward evaluating the stresses in the structure for proper design, it must be admitted that some appraisal of the external forces forms the other half of the "picture."

No doubt it is true that each tunnel project presents conditions in this respect peculiar to itself; but the writer is out of sympathy with the thought that because the determination of external forces is often more or less uncertain, in an absolute sense, theoretical studies, such as the author has presented, are of no practical value. In each undertaking more is learned, and uncertainties of yesterday become cleared up to-day. The value of theoretical investigation is that by its application in a comparative manner, the experience gained by the construction of works successfully accomplished may be carried over to present problems of projected work. The theory provides the vehicle. In other words, theoretical analyses permit of comparing tunnels of different sizes and types under approximately like conditions. In order to emphasize this the writer ventures to review, as briefly as possible, the main results of the Holland Tunnel studies, after which he will illustrate one phase of this work by considering the example shown by the author in Fig. 5.

---

[7] Designing Engr., New York Board of Water Supply, New York, N. Y.

The comparative studies were made mainly on the Pennsylvania Tunnel tube, as being most similar in kind of material, along with the tunnel tube considered, with others suggested. Extensive stress analyses were made by means of the method of least work and the method of deflections. Studies of the local stresses at the joints, both end and side, were based upon the results of these analyses. The cast-iron ring containing the entire internal structure and the cast-iron ring alone (as it would be during construction), with and without compressed air, were subject to the investigation. The depths over the top of the tunnel ring which gave the probable, greatest loadings, were 31 ft of silt beneath 38 ft of water, and the weights of silt and water were taken, respectively, at 104 and 64 lb per cu ft.

Due to the wide variations in the behavior of the silt of the Hudson River, as had been observed by different people at different times and under varying conditions, diverse opinions existed as to the actual forces that might be expected to be active externally. This is explainable if one considers the noticeable variation in the consistency, composition, water content, and weight of silt, after the violent disturbance of the shoving of the shield and then after a considerable time during which it has become quiescent around the tube. To include material of varying consistency, Rankine's theory of earth pressure was applied, through varying "angles of repose," although it was well recognized that that theory did not include the tenacity, or cohesion inherent to a more or less determinable degree, in the river silt. (Subsequent experiments disclosed a value reaching 0.4 lb per sq in., with a water content of 55% by volume. This value was indicated by a computation to contribute toward offsetting the tendency to rise because, by the Rankine theory, the result was that in some cases the weights of the tunnel ring alone, with the overlying material bearing upon it, were less than the upward, active pressures of the silt.)

Where "floatation" was indicated, due compensation was made by the distribution of a uniform load either at the top or bottom, as required, before proceeding with an analysis.

During construction, silt pressures were observed around the tube over a considerable period of time, by specially designed pressure gages, the tubes of which were let through the grout holes of the ring castings. Concurrently with these observations weight and water content determinations were made. The silt weight ranged from 93 to 114 lb per cu ft and the water content, from 52% to 64% by volume. Laboratory tests followed on transmission of conjugate pressures, whence as an index, angles of repose were computed. These angles varied between 1° 45′ and 2° 40′. The pressure gages in the tunnel disclosed that these angles were less at the top than at the bottom of the ring. The recent advance in the realm of "soil physics" gives promise, along these lines, of clarifying much that, in the initial stages of the Holland Tunnel construction, was more or less speculative and rendered the minds of some engineers skeptical of theoretical analyses.

In mentioning the Holland Tunnel, the author referred to high tensile steel in the tie-rods. It is believed that this tunnel was the first to have the tie-rods introduced. The tunnel ring bolts were also of the same material. It might be of interest to note in this connection that the idea for the use of high tensile steel in the Holland Tunnel, for this purpose, was proposed originally in December, 1920, by Ralph Smillie, M. Am. Soc. C. E., then Designing Engineer on the Tunnel Staff. There were several other features of design besides the bolts and tie-rods which were developed by the comparative studies made possible by the analyses. The segments of cast iron and steel were thickened at the corners of their flanges, which insured better castings and reduced local stresses in the flanges. It had been demonstrated that changing the location of the bolts connecting the end flanges of the ring segments, by moving them nearer to the inner sides of the web and side flanges of the segment, resulted in a more rigid joint and, consequently, a stiffer tunnel ring. Furthermore, it was proved that the lower middle bolt, then customary in end-flange design, was entirely inutile; but only with the introduction of the high tensile steel and corresponding decrease in bolt diameter were these innovations made possible. The bolts were tightened to an initial stress of 25 000 lb per sq in. and both the saving in bolt and tie-rod metal, together with a great reduction in the necessity of bolt tightening after each shove of the shield, amply justified the modifications in design. The effect of the tie-rods was approximated by supplemental calculations, which indicated a reduction in flexure in the ring by about one-half to nearly two-thirds, from that without their restraining effect.

The interest in the "loading" applied by the author was aroused by Fig. 5, in his exemplification of the application of the equations, illustrating the writer's contention of the affinity of the conditions surrounding a tunnel to stress analyses. Fig. 5, however, indicates that the example loading is fluid in nature, or that the Rankine angle of repose is zero. Furthermore, it is presumable that the dead weight of the tube is equal to the difference between the upward and downward vertical forces. For this reason the writer would be interested to learn of the actual conditions of loading assumed by the author, if those given do not rightly reflect them.

Table 1 serves to compare the moments in the Posey Tube between Oakland and Alameda, Calif., with one of cast iron, of the same outside diameter (37 ft), first under the loading inferred from Fig. 5 and then under the weight of material surrounding the Holland Tube as assumed for that tunnel, and with an angle of repose of 3 degrees. As a measure

TABLE 1.—Comparison of Maximum Moments in Tunnel Rings

Tunnel	For a Load, W_1, in Pounds per Cubic Foot, of:	
Angle of repose, ϕ	53.7	104
	0°	3°
Posey	24 500	20 000
Cast iron	1 100	36 000

for comparison, the maximum bending moments for each have been computed, without tie-rod restraint, by the following equation:

$$M = w{\cdot}D\,a + \left(1 - k - \frac{D}{H_s}b\right)\frac{W_1\,H_s\,D^2}{c}\;\ldots\ldots\ldots\ldots(31)$$

in which: M = maximum bending moment (in foot-pounds) in a tunnel ring 1 ft long; w = weight of tunnel, in pounds per linear foot; D = external diameter of tunnel ring, in feet; H_s = depth, in feet, of the center of the tunnel ring below the surface of the silt (the depth of water above is reduced to an equivalent depth of silt, which is added to the actual depth of silt); W_1 = weight of 1 cu ft of silt or material, in pounds; a, b, and c are constants; and:

$$k = \frac{1 - \sin\phi}{1 + \sin\phi}\;\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

in which ϕ = the angle of repose of the material surrounding the ring. Values of the constants, a, b, and c, for use in Equation (31) are given in Table 2. It should be borne in mind that Equation (31) yields only the value (not the location) of the maximum bending moment. A negative moment in an answer signifies only a reversal from the moments that have a plus sign.

TABLE 2.—Value of Constants for Use in Equation (31)

5°-30′	0.0275	0.4125	16.20	0.176	11°-0′	0.0326	0.4805	15.97	0.321
5°-45′	0.0263	0.4040	15.96	0.182	12°-0′	0.0327	0.4862	15.83	0.344
6°-0′	0.0411	0.5305	18.90	0.189	13°-0′	0.0328	0.4919	15.70	0.368
6°-30′	0.0359	0.4835	17.85	0.204	14°-0′	0.0329	0.4975	15.57	0.390
7°-0′	0.0307	0.4440	16.86	0.218	15°-0′	0.0330	0.5030	15.43	0.411

Fig. 5 indicates that the specific gravity of the material appears to be only 0.86. The head on the center of the 37-ft tube is 89.5 ft; its weight is 73 500 lb per lin ft, the weight of material around it, 53.7 lb per cu ft, and, the angle of repose, first 0° and second, 3 degrees.

The weight of a cast-iron tube, correspondingly, should be about 56 000 lb per lin ft. The results in Table 1 indicate that the Posey Tube sustains less flexure in the heavier cohesive material, whereas the cast-iron tube fares better in the liquid. No doubt it would float; but this has not been considered in the example.

Equation (31) was derived and constants computed as an epitome, as it were, of the studies alluded to by the writer. It may be used directly for fairly close approximations of values for tunnels of different sizes and weights and depths of submergence. Curves in terms of angles of repose and the moments as arguments may then be plotted and comparisons made.

The maximum bending moment usually occurs at the crown or invert although it has been found at the haunches, depending upon conditions, and occasionally between the crown and the haunch. Moments at the haunches are of opposite sign to those at the crown and invert, and the usual assumption is to consider moments to be positive when producing compression at the "extrados" of the ring, and negative if they produce tension.

A. A. EREMIN,[8] ASSOC. M. AM. SOC. C. E. (by letter).—The favorable response to the method of analysis presented in this paper is gratifying. The discussion contains much valuable information and constructive criticism.

FIG. 8.—TYPICAL TUBE LOADING

Equations (28) to (30) for horizontal displacement at Point x, y (Fig. 6), as presented by Mr. Peery, are correct. However, the computations of the horizontal displacements of the tube may be greatly simplified. For convenience of reference the left half of the tube, with Point P defined by the co-ordinates, x_1 and y_1, is shown in Fig. 7. The elastic center of the tube and the origin of the co-ordinates, x and y, are at the center. The vertical distance of the point, P, to the horizontal diameter of the tube, y_1, expressed as a proportion of the radius, is:

---

[8] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

$$y_1 = k\,r \qquad (33)$$

Therefore, the vertical distance from some point, x, y, on the shell to Point P, Fig. 7, is,

$$(y_1 - y) = r\,(k - \cos\theta) \qquad (34)$$

and the horizontal displacement at Point P on the left half of the tube fixed at the invert, Fig. 7, is,

$$\Delta_{0u} = r\int M\,(k - \cos\theta)\,dw + \int H\cos^2\theta\,dv + \int V\sin\theta\cos\theta\,dv$$

$$- H_0\left[r^2\int (k - \cos\theta)\cos\theta\,dw + \int \cos^2\theta\,dv\right] - M_0\,r\int (k - \cos\theta)\,dw. \qquad (35)$$

For practical purposes in computing horizontal displacements the influence of direct and shear stresses may be neglected without serious error. Therefore, Equation (35) may be written,

$$\Delta_{0u} = r\int M\,(k - \cos\theta)\,dw - H_0\,r^2\int (k - \cos\theta)\cos\theta\,dw$$

$$- M_0\,r\int (k - \cos\theta)\,dw \qquad (36)$$

Horizontal displacements can be computed more quickly by Equation (36) than by Equation (29). Furthermore Equation (36) involves integral terms similar to those in formulas for computing the redundant forces at the elastic center of a tunnel tube. The horizontal displacement of the left half of a tube, loaded with a force equal to unity ($X_1 = 1$) and acting along the upper tie-rod (see Fig. 7), or with any other loading, may be determined by Equation (36). The bending moment at any point, x, y, on the left half of a tube loaded with a force, $X_1 = 1$ (Fig. 7), is,

$$M = r\,(k - \cos\theta) \qquad (37)$$

In computing the horizontal displacement of the tube at Point P by Equation (36), each term containing an integral may be computed separately. Substituting the bending moment from Equation (37) in Equation (36), the first term in the latter is,

$$B_1 = r^2\int_{\pi}^{\theta_p} (k - \cos\theta)^2\,dw \qquad (38)$$

Integrating and simplifying,

$$B_1 = \frac{r^2}{E\,I}\left[k\,\pi + \frac{\pi}{2} - k^2\,\theta_p + 2\,k\sin\theta_p - \frac{1}{2}\,(\theta_p + \sin\theta_p\cos\theta_p)\right] \qquad (39)$$

Integrating and simplifying the second term of Equation (36), B_2 is:

$$B_2 = H_0 r^2 \int_{\pi}^{\theta_p} (k - \cos\theta) \cos\theta \, dw$$

$$= \frac{H_0 r^3}{E I} \left[- \frac{\pi}{2} - k \sin\theta + \frac{1}{2} (\theta_p + \sin\theta_p \cos\theta_p) \right] \ldots\ldots\ldots (40)$$

Integrating and simplifying the third term of Equation (36), B_3 is:

$$B_3 = M_0 r \int_{\pi}^{\theta_p} (k - \cos\theta) \, dw = \frac{M r^2}{E I} (k \pi - k \theta_p + \sin\theta_p) \ldots. (41)$$

Therefore, the horizontal displacement at Point P, Fig. 7, as computed by Equations (36) to (41) is,

$$\Delta_{0u} = B_1 + B_2 + B_3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Information concerning mud pressures on subaqueous tunnels, as given by Mr. Brodie, is most interesting. It is true, as Mr. Brodie states, that the method of considering the distribution of external pressures in subaqueous tunnels "forms the other half of the 'picture'."

In Example 1, Fig. 5, the loadings are assumed. It may be interesting to compare them with the specified external loading used in the design of the Posey Tunnel. Water pressure on that structure was considered as acting (independent of earth pressure) radially over the entire circumference. The vertical pressure on the top was considered equal to the total weight of water, at 64 lb per cu ft, plus the weight of the submerged earth at 62 lb per cu ft. The intensity of the lateral pressure at any section was assumed equal to total vertical pressure, excluding water pressure, multiplied by 33%, plus the intensity of water pressure. This also agrees with lateral pressure computed with Rankine's formula for wet sand with an angle of repose of 30° recommended by the late Milo S. Ketchum, Hon. M. Am. Soc. C. E.[9]

Assume the tunnel in Example 1 to be placed 48 ft below the water surface, as shown in Fig. 8. The top of the earth fill is 12 ft above the top of the tunnel. Therefore, the vertical pressure on top of the tube is $64 \times 48 + 62 \times 12 = 3\,816$ lb per sq ft. The side pressure at the top of the tube is $64 \times 48 + 62 \times 12 \times 0.33 = 3\,318$ lb per sq ft. The side pressure at the bottom is $64 \times 82.5 + 62 \times 46.5 \times 0.33 = 6\,231$ lb per sq ft.

Assuming the weight of tube to be equal to the buoyant force of the submerged tube, the vertical pressure at the invert will be the same as that at the top. If the tube is filled with water, and if the earth fill is placed directly on top of the tube, the vertical pressure on the invert will be greater than that on top by an amount equal to the weight of the submerged tube. To simplify computations in Example 1 the loading on the tube was as shown in Fig. 5. Evidently, this loading gives greater stress in the tie-rods than that in Fig. 8. The exact loading on subaqueous tunnels varies with the method of construction, the supporting foundation beneath the finished tunnel tube in place, the variation of the water level, and the plastic flow in the earth and the mud fill on top of the tube. Interesting effects of the plastic flow of mud on the external pressures and deformations of the Hudson and Manhattan Railroad tubes were observed during the construction of the cast-steel rings. Perfectly circular steel rings, when shoved forward under pressure by means of jacks, were changed in form by the lengthening of their vertical diameters and the shortening of their horizontal diameters. After the plastic flow of mud had occurred the shape was reversed; the vertical diameter decreased, and the horizontal diameter increased. By tightening the steel tie-rods the tube rings may be returned to their original form. Equation (31) gives the value of the maximum bending moment in the circular tunnel tube without tie-rods. This bending moment may occur at the crown, at the invert, or at the haunch section as stated by Mr. Brodie. It is to be regretted that Mr. Brodie did not give sufficient information to permit one to check Equation (31). The need for a more determinate method of computing bending moments at desired sections is self-evident. The redundant force, H_0, and the bending moment, M_0, at the elastic center of the tunnel tube without tie-rods may be computed by Equations (25) and (26), respectively. The bending moment, M_1, at any point on the tube without tie-rods, by Equation (16), is:

---

[9] "The Design of Walls, Bins, and Grain Elevators," by Milo S. Ketchum, Third Edition, p. 73.

$$M_1 = - M + H_0 y + M_0 \ldots\ldots\ldots\ldots\ldots\ldots (43)$$

The maximum bending moment may be determined algebraically by Equation (43), with the external loading expressed by a continuous function or by plotting a force polygon. In practice, however, with a few trial computations, the maximum bending moment in a tube may be determined without much effort.

A method of computing stresses in subaqueous tunnel tubes without tie-rods,[10] has recently been advanced by M. Alfano, who assumes the origin of the co-ordinates at the invert instead of that at the center of the tube. However, he failed to show any advantages in computing stresses with the origin of co-ordinates selected in this manner.

DEFLECTIONS BY GEOMETRY

BY DAVID B. HALL[1], ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. J. MCGAW, L. E. GRINTER, RALPH W. STEWART, WILLIAM BERTWELL, AND DAVID B. HALL.

SYNOPSIS

The fundamental method for finding deflections is by geometry, rather than by the law of conservation of energy or the principle of least work. The few simple rules that are necessary in a geometrical analysis are given in this paper, and are illustrated by developing methods for calculating influence lines for such structures as arches, and deflections in trusses.

GENERAL THEORY

For the engineer who is constantly dealing with stresses, but meets only occasionally with deflections or statically indeterminate structures, the methods of calculating deflections in terms of imaginary forces are of great assistance. They enable him to make computations with a minimum knowledge of the subject of deflections. For this same reason, however, such indirect methods as that of least work, or of elastic weights, tend to stand in the way of acquiring real facility in the subject.

A simple illustration will show the real inward nature of the problem. Consider the four following problems.

Problem 1.—Determine the Force X, in Fig. 1, by the Principles of Statics.—The solution is evidently to take moments about the support; whence $X = 2$ lb.

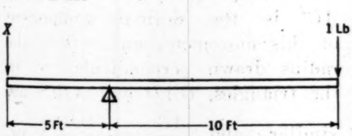

FIG. 1.—MECHANICS PROBLEM.

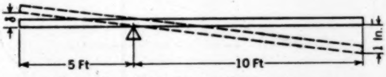

FIG. 2.—GEOMETRY PROBLEM.

Problem 2.—Determine the Distance, δ_x, in Fig. 2, by Geometry.—From similar triangles it is evident that $\delta = 0.5$ in.

NOTE.—Published in December, 1936, *Proceedings*.

[1] Detailer, Ash-Howard-Needles & Tammen, New York, N. Y.

Problem 3.—Determine the Force, X, Fig. 1, in Some Manner Other Than by Statics.—If the force of 1 lb is balanced by the unknown force, X, and the lever is rotated slightly, one side will gain, and the other side will lose, energy. According to the law of conservation of energy, these two changes must be equal. Therefore, continuing from the solution of Problem 2, $X \times 0.5$ in. $= 1$ lb $\times$ 1 in.; and, $X = 2$ lb.

Problem 4.—Determine the Deflection δ, Fig. 2, in Some Manner Other Than by Geometry.—Once more using the law of conservation of energy, apply a force on the left end and find by statics the force on the right end to balance it; then find how far the first force must move to balance the energy gained or lost by the second force in moving 1 in. This distance will be 0.5 in.

Comment.—In the foregoing group of problems it is quite obvious that the simplest solution of the mechanics problem is by mechanics and the simplest solution of the geometrical problem is by geometry. The solution presented in Problem 4, however, is often referred to as the fundamental method of solving deflection problems. It is none other than the method of work. By the more usual method of presentation, the force corresponding to that on the right side of the lever would be furnished by elastic members, and, therefore, both it and the force on the left would be functions of the deflections and the energy would be determined by integral calculus, although these complications seem to be irrelevant.

The group of problems suggests one constructive idea, however: When new methods for applying the geometry of deflections are being sought, there will usually be similar familiar methods for solving corresponding mechanics problems to serve, not as substitutes, but as guides.

Probably the most important theorem of the geometry of deflections is one which bears a very close resemblance to the principle of moments:

Theorem 1.—If a body rotates about a point through an infinitesimal angle (in ordinary structures all deflections are treated as infinitesimal quantities), the component in any direction of the movement of any point in the body is proportional to the perpendicular distance from the line of that component to the center of rotation.

The proof of Theorem 1 is quite simple. In Fig. 3 it will be seen, in the first place, that the actual motion of a point such as A is at right angles to the radius, OA, and proportional to its length. (The motion is numerically equal to $\overline{OA} \times \alpha$.) If AC is the desired component of this movement, and OD is the radius drawn perpendicular to it, the triangles, OAD and ABC, are similar, and $\frac{\overline{AC}}{\overline{AB}} = \frac{\overline{OD}}{\overline{OA}}$; or,

$$\overline{AC} = \frac{\overline{OA} \times \alpha \times \overline{OD}}{\overline{OA}} = OD \times \alpha.$$

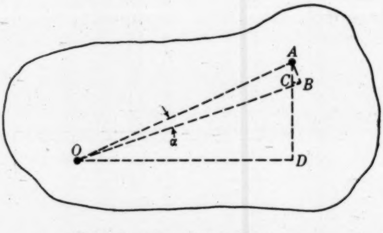

FIG. 3.—ROTATION THEOREM

When dealing with deflections in terms of vertical and horizontal components, the foregoing theorem can be stated more conveniently as follows:

Theorem 2.—When a body rotates about a point, the vertical displacement of any point is proportional to its horizontal distance from the center of rotation, and the horizontal displacement is proportional to its vertical distance.

DEFLECTIONS OF BEAMS

The simplest type of beam to investigate is a cantilever. Consider the beam in Fig. 4. Suppose that the moment in the shaded area causes this portion of the beam to bend through an angle, α. (This angle can be calculated by the well known formula, $\alpha = \frac{M\,dL}{E\,I}$, in which dL is the length of the portion considered; M is the moment; E, the modulus of elasticity; and I, the moment of inertia.) Then Theorem 2 can be applied directly to determine the deflection at the end contributed by this part of the beam. The vertical deflection is $x\,\alpha$, or $\frac{M\,dL}{E\,I}\,x$, and the horizontal deflection is $\frac{M\,dL}{E\,I}\,y$. To find the complete deflection, it is necessary to add the contributions from each part of the beam, integrating by calculus if possible, or by dividing the beam into a number of sections and treating the average properties of each section.

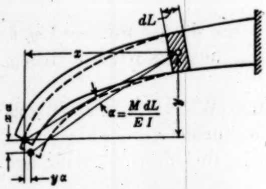

FIG. 4.—DEFLECTION OF A CANTILEVER.

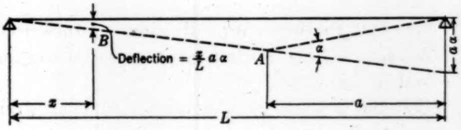

FIG. 5.—DEFLDCTION OF A SIMPLE BEAM.

To find the moments in a cantilever it is only necessary to multiply the loads and their lever arms. To find the moments in a simple beam an additional step is required: (1) Take moments about one support and find one reaction; and (2) find the moment caused by this reaction. Similarly, an extra step is required in finding deflections in a simple beam. The process is illustrated in Fig. 5. Bending through an angle, $\alpha \left(= \frac{M\,dL}{E\,I}\right)$, at Point A would produce an upward deflection, $a\,\alpha$, at the right end if the left part were held fast. If the beam were then rotated as a whole until the right end rested on its support, the beam would assume the position which it actually does occupy, and the proportionate deflection at Point B would be $\frac{x}{L}\,a\,\alpha$.

In both of the foregoing examples it will be discovered that the coefficient of $\frac{M\,dL}{E\,I}$ is identical to the moment, m, which a unit load applied where the deflection is measured would produce at the point that is bending. This again illustrates the connection between the methods of Problems 2 and 4, and forms the basis of the dummy load formula:

$$\delta = \int \frac{M\,m\,dL}{E\,I} \quad \text{......................} (1)$$

There are two general methods of determining deflections: The foregoing, which might be referred to as single integration, and the method of double integration. The second method is particularly adapted to determining deflections at all the division points of an irregular beam such as an arch. In order to have something definite and clear cut upon which to perform the various operations that are involved, the beam should be visualized in the following manner:

1.—Cut the beam into divisions as indicated by the dotted lines in Fig. 6. (The dotted lines are necessary for the explanation but are not essential in actual design.)

2.—Set a point in the middle of each division. When the beam is subjected to bending the faces of Division 4, say, are turned through a certain angle relative to each other, the part of the axis in this division being bent in a curve. This angle is $\frac{M\ dL}{E\ I}$, in which dL is the length of the division. The same happens in each of the other divisions.

3.—Instead of considering the divisions curved by the moments, the beam is assumed to consist of a series of straight lines from point to point and the bending to consist of a change in the angles at the joints in these lines. With the beam thus articulated it is a simple matter to visualize any operation that has to be performed.

FIG. 7.—DEFLECTION BY DOUBLE INTEGRATION.

The deflection of a cantilever by double integration is illustrated in Fig. 7. The process is exactly the same for a curved beam. A straight beam was illustrated to avoid confusing the reader with two sets of angles. For any other beam than a cantilever the best method is to determine the rotation at some point first and then proceed from there to sum up the angles at the joints. For a symmetrical simple beam, symmetrically loaded, this is accomplished by starting at the center where the slope is zero. It may be noted that the point of initial slope and the point of zero deflection do not need to be the same; the first summation can proceed in one direction, and the second in the opposite direction.

Influence Lines for Arches.—Calculation of the influence line for the thrust in a symmetrical two-hinged arch (see Fig. 8) is a good illustration of the foregoing method. Instead of placing a unit load at successive points to find the displacement of the hinges, the vertical deflections of points along the arch due to a unit thrust at the hinges may be calculated, since by the theorem of reciprocal displacements both are alike. In Table 1 it will be noted that the lines are double-spaced. Entries opposite the points refer in some manner to the individual points (co-ordinates, angles, etc.), whereas entries between points refer to the lines joining them (slopes, increments of deflection, etc.). For divisions of equal length, $\frac{dL}{EI}$ is proportional to $\frac{1}{t^3}$, in which t is the thickness of the section. For a unit thrust, $M = y$, and

$2\Sigma \frac{y^2}{t^3}$	....	...	....	...	...	627.2	..	.. ...	......	....	....

$\frac{M\ dL}{E\ I}$ is equivalent to $\frac{y}{t^3}$. The horizontal displacement between the hinges is equal to $\sum \frac{y^2}{t^3}$, and the influence line is obtained by dividing the deflections for unit loads by this displacement.

As these operations become more familiar, increasingly difficult problems can be solved. For example, apply a horizontal force of 1 lb at Point O, in Fig. 9. The moment at any point, P, will be 1 lb × y, and the movement at Point O will be, $\sum \frac{y^2\,dL}{E\,I}$, horizontally, and $\sum \frac{x\,y\,dL}{E\,I}$, vertically. Similarly, a vertical force of 1 lb will produce a vertical movement of $\sum \frac{x^2\,dL}{E\,I}$ and a horizontal movement of $\sum \frac{x\,y\,dL}{E\,I}$.

When these deflections have been determined it is a simple matter to compute a combination of vertical and horizontal forces at Point O which will cause a horizontal deflection of one unit and no vertical deflection. The formulas for this condition, and for a unit vertical deflection, are as follows:

For a unit horizontal deflection:

$$H = \frac{\Sigma\ (x^2\,G)}{B} \quad \text{..........................} (2)$$

and,

$$V = \frac{\Sigma\ (x\,y\,G)}{B} \quad \text{..........................} (3)$$

and, for a vertical deflection:

$$H = \frac{\Sigma\ (x\,y\,G)}{B} \quad \text{..........................} (4)$$

and,

$$V = \frac{\Sigma\ (y^2\,G)}{B} \quad \text{..........................} (5)$$

in which $G = \frac{dL}{E\,I}$; and.

$$B = \Sigma\ (x^2\,G)\ \Sigma\ (y^2\,G) - \left[\Sigma\ (x\,y\,G)\right]^2 \quad \text{................} (6)$$

Furthermore, it is not difficult to compute the moments and, in turn, the deflections at a succession of points along the structure due to these forces at Point O. These deflections constitute the influence line for the horizontal reaction at Point O in a structure fixed at Point A (Fig. 9) and hinged at Point O, because the foregoing process is the mathematical equivalent of the Beggs mechanical method for obtaining influence lines.

This principle will be illustrated by the calculation of the constants for unsymmetrical beams of variable section. If the right end of Beam AB

(Fig. 10(*a*)) is fixed and the left end is rotated through a unit angle, the resulting end moments can be called stiffness factors. The moment at End *A* will be denoted as K_A; the moment at End *B* will be denoted as K_{AB} (or K_{BA},

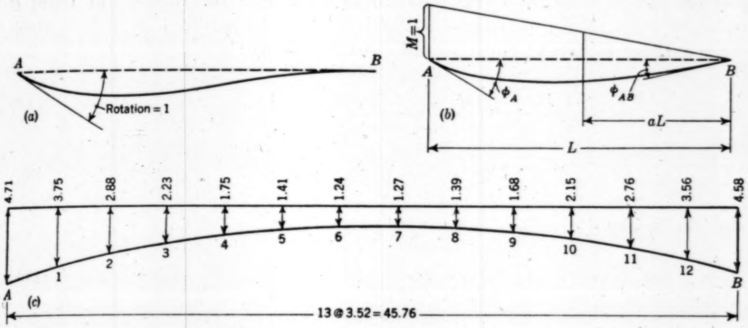

FIG. 10.

since it will be found that the fixed-end moment for either end, when the opposite end is rotated, is the same). Similarly, if End *A* is fixed and End *B* is given a unit rotation, the moment at End *B* will be K_B.

For the moment distribution method, K_A and K_B are the usual stiffness factors, and $\frac{K_{AB}}{K_A}$ and $\frac{K_{AB}}{K_B}$ are the carry-over factors. For the slope deflection method,

$$M_{AB} = K_A(\theta_A - R) + K_{AB}(\theta_B - R) + C_{AB} \dots\dots\dots\dots (7)$$

and,

$$M_{BA} = K_B(\theta_B - R) + K_{AB}(\theta_A - R) + C_{BA} \dots\dots\dots\dots (8)$$

in which C_{AB} and C_{BA} are fixed beam moments, the signs being algebraic.

The method of obtaining the foregoing *K*-factors is as follows: The clockwise rotation of End *A* in the simple beam in Fig. 10(*b*) is equal to the deflection of End *B* from the tangent at End *A*, divided by *L*, and can readily be shown to be:

$$\phi_A = \int \frac{a^2\, dL}{E\, I} \dots\dots\dots\dots (9)$$

or for finite divisions,

$$\phi_A = \frac{\Sigma\, a^2\, dL}{E\, I} \dots\dots\dots\dots (10)$$

This rotation will be referred to as ϕ_A. The counterclockwise rotation at Point *B*, is equal to:

$$\phi_{AB} = \frac{\Sigma\, a\,(1 - a)\, dL}{E\, I} \dots\dots\dots\dots (11)$$

For a unit moment at Point B, $\phi_B = \sum \frac{(1-a)^2\, dL}{E\, I}$, and ϕ_{BA} is the same as ϕ_{AB}. To obtain the stiffness factors, K_A and K_{AB}, it is simply necessary to make the rotation at Point A equal to unity and the rotation at Point B equal to zero, thus producing the condition illustrated in Fig. 10(a), which defined these factors. The necessary equations are:

$$M_A\, \phi_A - M_{AB}\, \phi_{AB} = 1 \quad \text{.....................(12)}$$

and,

$$M_A\, \phi_{AB} - M_{AB}\, \phi_B = 0 \quad \text{.....................(13)}$$

and the solution gives,

$$M_A = K_A = \frac{\phi_B}{\phi_A\, \phi_B - (\phi_{AB})^2} = \frac{\phi_B}{D} \quad \text{..............(14)}$$

and,

$$M_{AB} = K_{AB} = \frac{\phi_{AB}}{D} \quad \text{.....................(15)}$$

Similarly,

$$K_B = \frac{\phi_A}{D} \quad \text{.........................(16)}$$

A typical beam is shown in Fig. 10(c), and the evaluation of these constants for this beam is contained in Table 2. It will be noticed that multiplying or dividing at strategic points by the number of divisions (13) facilitates the numerical work. Referring to the summation of Table 2:

TABLE 2.—EVALUATION OF CONSTANTS FOR AN UNSYMMETRICAL BEAM (SEE FIG. 10(c))

Summation...	.....	...	..	...	396.50	331.50	409.94

* One-half section.

$$13^4\,\phi_A\,\phi_B = \text{product of Columns (5) and (7)} = 162\,541$$

$$13^4\,\phi_{AB}^2 = \text{Column (6) squared} = 109\,892$$

$$13^4\,D = 13^4\,(\phi_A\,\phi_B - \phi_{AB}^2) = 52\,649$$

Finally, the stiffness factors are:

$$K_A = 409.94 \times \frac{13^3}{52\,649} = 1.31588$$

$$K_{AB} = 331.50 \times \frac{13^3}{52\,649} = 1.06409$$

and,

$$K_B = 396.50 \times \frac{13^3}{52\,649} = 1.27274$$

The stiffness factors having been calculated, it is now a simple matter to apply the equivalent of the Beggs method for finding the fixed-beam end moments. To obtain actual numerical values for the moment at Point A, the deflections must be determined while End A is rotated through a unit angle and End B is held fixed, exactly the same as in a mechanical model. Referring to Fig. 10(a), it is evident that this condition can be realized by applying at End A the moment, K_A (= 1.31588), and at End B the moment, K_{AB} (= 1.06409). Since one of the operations will consist of multiplying

the various slopes by dL (see Fig. 7), it will save work to do this in advance, by using the moments, $K_A \times 3.52 = 4.6319$, and $K_{AB} \times 3.52 = 3.7456$. The moments along the beam vary between these two values by thirteen equal increments, so that they are very easily tabulated (see Column (2), Table 3). Multiplying by $\dfrac{dL}{EI}\left(\text{or, } \dfrac{dL}{t^3}\right)$ gives the angle at each joint; one summation gives the slope of each section (note that the slope at End A equals 3.52 as a check); and the second summation gives the ordinates of the influence line. A similar operation gives the same data for End B (Columns (6) to (9), Table 3).

The values of the moment increments are:

$$
\begin{array}{lcl}
\text{For Column (2):} & & \text{For Column (6):}\\
3.52\,K_A = 4.6319 & & 3.52\,K_B = 4.4800\\
3.52\,K_{AB} = 3.7456 & & 3.7456\\
\hline
\phantom{3.52\,K_{AB} =}\ 8.3775 & & 8.2256
\end{array}
$$

$$
\text{Increment} = \frac{8.3775}{13} = 0.644423 \qquad \frac{8.2256}{13} = 0.632738
$$

This same method is well adapted to calculating influence lines for fixed arches, especially if the redundants are taken at the elastic center of the arch. It has been used successfully on unsymmetrical two-span arches, such as those illustrated in Fig. 11(a). In this case the statically determinate base system and the redundant forces, X, were assumed to be as shown in Fig. 11(b). The three deflections due to each of the three redundants were calculated; then, for each influence line, three simultaneous equations were solved to make the corresponding deflection unity and the other two deflections, zero; and through each of these stages a record was kept of the rotation of the top of the center pier, to serve as a starting point for summing up the changes in direction from point to point.

FIG. 11.—A TWO-SPAN FRAME.

TRUSS DEFLECTIONS

The geometry of trusses, if anything, is even simpler than the geometry of beams, since a few definite members take the place of continually changing infinitesimal elements. Most of the methods of stress calculation, both graphic and analytic, have some kind of a counterpart in deflection calculation. There is a distinction, however, in the case of resolution of forces or displacements at a joint. From the law of conservation of energy, it will be observed that the relation between displacements is the reciprocal of the relation between forces, since the product of forces and displacements must be constant. The relation of forces at a joint can be represented by a force triangle or polygon, and the relation between displacements, therefore, automatically cannot. This is the reason that Williot diagrams are inherently more complicated than stress diagrams. For this same reason the dummy load method expedites deflection calculations for single joints or panels.

For complete truss deflections it is preferable to deal with rotations, just as a majority of stress calculations are made by moments. Most of the conditions that can arise, are illustrated by Fig. 12. Consider the deflection at Point *A* due to a change in length of Member *CD*. The part of the truss bounded by Points *d, D, F,* and *f* will remain fixed in place. The part bounded by Points *d, C, A,* and *b* will rotate as a unit about Point *d.* The extent of this rotation is the stretch of Member *CD* divided by the perpendicular distance from *CD* to Point *d,* and the vertical movement of Point *A* (or any other point on the moving part of the truss) is equal to this rotation times the horizontal distance to Point *d.* If the member, *dE,* stretches, the polygon, *dDAb,* will rotate about Point *O.* This motion can also be treated as a combined translation and rotation about Point *D* or Point *E,* expressed entirely in terms of the dimensions of Panel *dDEe*[2].

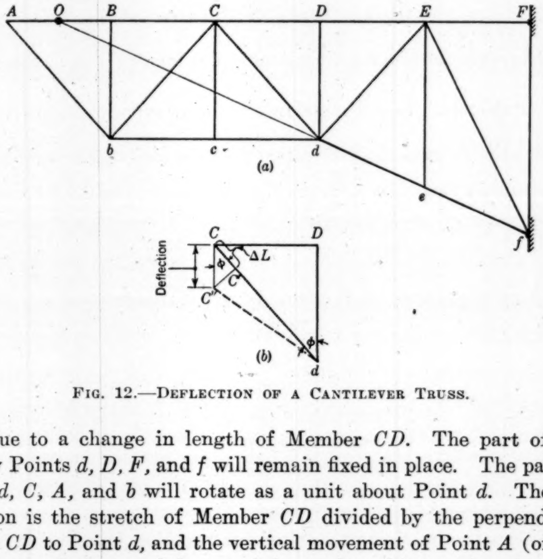

FIG. 12.—DEFLECTION OF A CANTILEVER TRUSS.

For a change in length of Member *Cd,* the rectangle, *dDCc,* is distorted into a parallelogram, and the remainder of the truss is displaced without rotating. The movement is equal to the change of length of Member *Cd* (ΔL)

---

times $\frac{\overline{d\,C}}{\overline{d\,D}}$ as shown in Fig. 12(*b*), because the triangle, *CC′ C″*, is similar to Triangle *dDC*, and $\frac{\overline{C\,C''}}{\overline{C\,C'}} = \frac{\overline{d\,C}}{\overline{d\,D}}$.

The actual systematic computation of the deflection of a simple truss is shown in Fig. 13 with Table 4. In Fig. 13, the upper values denote changes of length, ΔL; and the lower values denote the factor, $\frac{40}{50}\,\Delta\,L$, for chords and $\frac{64}{50}\,\Delta\,L$ for diagonals. In a simple truss of this type no algebraic signs are required since the deformations of all members contribute to downward deflection. An alternative method of solving this problem, based on single, instead of double, integration has been presented elsewhere[3] by the writer.

SCOPE OF THE GEOMETRICAL METHOD

Only a few specific applications of the theory of determining deflections by geometry have been presented herein. However, what the writer particularly wishes to emphasize is that a familiarity with the basic rules, comparable with the average engineer's familiarity with forces and moments, will make it possible to improvise methods for solving problems which formerly appeared to be quite difficult.

---

[3] *Engineering News-Record,* June 7, 1934, p. 746; and *Transactions,* Am. Soc. C. E., Vol. 102 (1937), p. 202.

For any one who is interested in acquiring proficiency in this method, a few suggested exercises are as follows:

(1) In a three-hinged arch, write the formula for the deflection at some point on one side due to an angle at some point on the other side. This involves one more operation than a simple beam, just as the simple beam requires one more operation than a cantilever.

(2) Devise a method for calculating the dead load moments in a two-hinged arch such as in Fig. 8. Then, find what the dead load moments will be if the base is fixed, not by beginning over again, but simply by finding the rotation of the base of the two-hinged arch and then eliminating it, using data on hand as much as possible.

DISCUSSION

A. J. McGaw,[4] Jun. Am. Soc. C. E. (by letter).—The author has focused much needed attention upon the principles of geometry as they affect structural action. Although equally accurate results may be obtained by the methods embracing the law of conservation of energy and the principles of least work, and although these methods are in many instances desirable as analytical procedures, they do side-track the geometry involved, which is so essential to complete understanding of the subject of indeterminacy. As a teaching tool, at least, the geometric method has much in its favor. The physical conception of structural deformation and the part played by geometry must, of necessity, go hand in hand. The formula-minded analyst, in many cases, fails to see his structure act. It is probably safe to state that analyses made under such conditions are dangerously likely to contain error. There is little to fear from the designer who can sketch the structure at hand in its deformed shape. It follows that an understanding of the principles of geometry as they affect structural action is highly desirable.

Along this same line of thought, it seems that the development of fundamental theory, through the utilization of geometric principles, may be extended advantageously to include Maxwell's law of reciprocal deflections. Surely, any haziness in one's mind concerning the truth and logic of this fundamental and much used tool will prevent, to a considerable extent, real mastery of the subject of indeterminacy. With this in mind, the writer has adapted the reasoning presented by the author to evolve a proof of Maxwell's law.

As in the paper, the beam, *AB*, in Fig. 14(*a*) has been assumed rigid, except at Point *G*. Due to the unit load at Point *D*, the moment, M_G, at Point *G*, has produced a rotation at that point through the angle, α_D, equal to:

$$M_G = \frac{x\,a}{L} \qquad \text{.........................(17)}$$

and since α_D is proportional to M_G,

$$M_G\,K = \alpha_D = \frac{x\,a\,K}{L} \qquad \text{....................(18)}$$

Furthermore, the ordinate, *BF*, in Fig. 14, equals,

$$\alpha_D\,a = \frac{x\,a^2 K}{L} \qquad \text{....................(19)}$$

and the deflection at Point *E* equals:

$$\delta_E = \frac{\overline{BF}\,x_E}{L} = \frac{x\,a^2\,x_E\,K}{L^2} \qquad \text{..................(20)}$$

---

[4] Instructor of Civ. Eng., Coll of Eng., Univ. of Wyoming, Laramie, Wyo.

Similarly, the deflection at Point D (Fig. 14(b)), with a unit load at Point E, may be obtained as follows:

$$\alpha_E = M_G\,K = \frac{x_E\,a\,K}{L} \qquad \text{(21)}$$

and, the ordinate, BF, is equal to:

$$\alpha_E\,a = \frac{x_E\,a^2 K}{L} \qquad \text{(22)}$$

and,

$$\delta_D = \frac{\overline{BF}\;x}{L} = \frac{x\,a^2\,K\,x_E}{L^2} \qquad \text{(23)}$$

Comparing Equations (20) and (23), $\delta_E = \delta_D$, which shows that the deflection at E due to a unit load at Point D equals the deflection at Point D due to a unit load at Point E. The flexure effects for all points along the beam must be summed up to obtain the total deflections. This is not necessary to the proof, however, since, obviously, the sums of equals must be equal.

That the vertical deflection at Point D caused by a unit moment at Point A (Fig. 15(a)) is equal to the rotation at Point A caused by a unit load at Point D (Fig. 15(b)) may be shown in a similar manner. A unit

FIG. 15

moment is applied at Point *A*, Fig. 15(*a*), and the corresponding moment diagram for the beam is shown in Fig. 15(*c*). Then:

$$\alpha_A = \frac{K\,a}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

and since Ordinate $BF = \alpha_A\,a$,

$$\overline{BF} = \frac{K\,a^2}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

The vertical deflection at Point *D*, Fig. 15(*a*), is then:

$$\delta_D = \frac{\overline{BF}\,x}{L} = \frac{K\,a^2\,x}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

The moment, M_G, at Point *G* (Fig. 15(*b*)), due to a unit load at Point *D*, is $\dfrac{x\,a}{L}$, and since $\alpha_D = K\,M_G$, it follows that:

$$\alpha_D = \frac{K\,x\,a}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

Again, Ordinate $BF = \alpha_D\,a$, and, therefore:

$$\overline{BF} = \frac{K\,x\,a^2}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

and Angle ϕ equals $\dfrac{\overline{BF}}{L}$, so that,

$$\phi = \frac{K\,x\,a^2}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

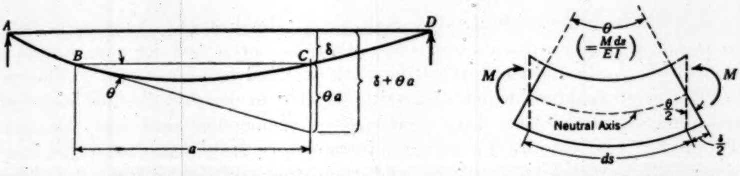
Comparing Equations (26) and (29), $\phi = \delta_D$, which shows that a rotation at Point *A* caused by a unit load at Point *D* equals the deflection at Point *D* due to a unit rotation at Point *A*.

L. E. Grinter,[5] M. Am. Soc. C. E. (by letter).—The determination of deflections by structural geometry, as described in this paper, will serve as an excellent antidote for the attitude among undergraduate and graduate students of structures that the subject of deflections must be treated in a rather "high-brow" manner. The author has discussed a large group of problems with little more theory than that involved in a discussion of the subject of radian measure. With this paper, the terms, "structural geometry", "geometry of structures", or "geometry of deflection", "come out into the open", without becoming camouflaged by association with the dozen or more methods of deflection computation that are in use.

For some years the writer has been using the term, "structural geometry", to indicate such geometric relationships as those involved in the sketches of Fig. 16, which seem to be encompassed by the author's term, "geometry of deflection." These relationships are so simple that they follow almost without proof and for this reason they form a proper introduction to the study of deflections. Furthermore, they involve no abstruse conceptions, such as the use of a "dummy" load, or the imaginary application of an $\frac{M}{EI}$ - loading. For the undergraduate student, or the sub-professional engineering employee, these geometric relationships are the proper starting point in a study of deflections. This, it seems, is also the author's belief. Textbooks on the strength of materials should emphasize such applications of structural geometry more decidedly than the common procedure of double integration. That authors of standard textbooks have always reversed this emphasis is one reason why undergraduate students, and even engineering graduates, often face the subject or the practice of indeterminate structural analysis and design with a complete lack of confidence.

---

[5] Director of Civ. Eng., and Dean, Graduate Div., Armour Inst. of Technology, Chicago, Ill.



(a) RELATIVE DEFLECTIONS (b) INTERNAL DISTORTION

FIG. 16.—STRUCTURAL GEOMETRY.

On the other hand, there is much to be said for the methods of virtual work, area moments, the conjugate beam, elastic weights for trusses, and the Williot-Mohr diagram. Each of these methods, in certain of its forms, offers a semi-automatic procedure of deflection computation, a very desirable feature where the process is to be repeated over and over as in the analysis of certain indeterminate structures. Furthermore, the method of virtual work, for example, can be used not only to find a deflection caused by flexure, but one caused by shear, torsion, or direct stress. It is also quite as applicable to the determination of rotations caused by any internal distortion. The author's conceptions of "geometry" are scarcely so extensive. For graduate study, then, assuming that the conceptions of structural geometry have been fixed in the student's mind in his undergraduate courses, the writer feels that the student should become familiar with each of the aforementioned methods. He should also learn that Castigliano's theorem is simply a reversed statement of virtual work (that is, a reversed order of the differentiation and integration), and he should be made to realize that such terms as elastic weights, moment weights, angle loads, etc., are all simply names for the same conception of an $\frac{M}{EI}$ - loading revised for application to trusses.

In other words, the most useful tool of deflection computation for the beginner is that method which is most nearly physical or visual; but the method that will be most useful to the experienced engineer may well be that which requires the least visualization and, therefore, tends to become most nearly automatic in its application. Here, therefore, is a conflict that will always appear. It explains why such intangible methods as virtual work and the conjugate beam are so widely useful and so widely used. Such methods are difficult to learn but easy to apply. When properly presented, the Williot-Mohr diagram can be shown to be both visual and semi-automatic. The author has presented the geometrical method as a very simple visual procedure. To interest the practical engineer, he should also emphasize its possibilities for rapid semi-automatic computations, such as those presented in Table 1.

Ralph W. Stewart,[6] M. Am. Soc. C. E. (by letter).—Adhering closely to sound conventional methods, the author has presented an able introduction to his theme and has carried the work outlined to a successful conclusion.

The only weakness which the writer is able to discover is that a part of the analysis could have been made more geometrical and less laborious. To illustrate this point the author's introductory statements regarding rotations will be slightly expanded and then the stiffness factors and other constants for the beam of variable and unsymmetrical section, represented by Fig. 10, will be developed in a more purely geometrical manner, which will substantially reduce the arithmetical work.

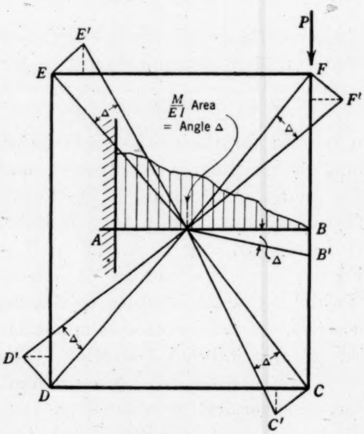


Fig. 17

Fig. 17 represents the application of the author's rotation Theorems 1 and 2, illustrated by Fig. 3, with reference to a specific cantilever beam and some connecting members, rather than with reference to an abstract point, *O*, which is not tied in to any structure. The rectangular frame, *CDEF*, is free except for its integral connection with the beam at Point *B*. It may be conceived that Sides *EF* and *DC* pass through slots in the wall which fixes the beam at Point *A*.

If now, a load, *P*, is applied either over Point *B*, or at any point on the beam, a cantilever moment will be created. Regardless as to whether the beam section and its modulus of elasticity are constant or variable, the computer can lay out the $\frac{M}{EI}$-diagram due to this cantilever moment, if the make-up of the beam is known. The point where the center of gravity of this $\frac{M}{EI}$-diagram is projected upon the unsprung axis of the beam will now be the center of rotation about which the deflection of Point *B* and all points of the tributary frame occur. This center of rotation is a fixed point independent of the magnitude of the load. Its location, for any beam, can be determined by computing the $\frac{M}{EI}$-diagram for a trial load or a trial moment when the real load or the real moment is known as to position, but not as to amount. The rotation, expressed as an angle, is equal numerically to the total area of the $\frac{M}{EI}$-diagram.

---

[6] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

In Fig. 17 the rotation is represented by the angle, Δ, and the movement of each lettered point on the frame is indicated by the primed letters. The formulas for the movement of each point are correctly stated by the author. A beam having two end moments will have two such centers of rotation, which, if the beam has end slopes, will be projected on the end slope lines instead of the unsprung axis.

A paper explaining the geometrical methods of analyzing the flexure of continuous structures by means of a series of lines connecting these centers of rotation, has been published.[7]

4	9	1.678	15.102	9	4	0.844	3.376	Summation....		15.945	112.802

* See Fig. 10. † $\frac{0.124}{2} \times 12\frac{2}{3} = 0.788$.

In an analysis such as that of the variable beam (Fig. 10), it is better to find these centers of rotation and the ratio between an end moment and its corresponding angle of rotation and subsequently to treat the flexure in the span due to each end moment as a single item rather than as a series of small items each resulting from the curvature of a separate increment, *dl*. This permits the mechanics of the problem to be transformed into a purer form of geometry and also reduces the number of arithmetical operations.

To compute the constant for the beam in Fig. 10 apply a trial end moment of 13 at End *A* with End *B* assumed to be hinged. In Table 5, Columns (1) represent the moment at each division point of the beam and Columns (2), the $\frac{M}{t^3}$-value at each division point. The $\frac{M}{t^3}$-area, taking each division length as unity instead of 3.52, is the summation of

---

[7] "The Analysis of Continuous Structures by Traversing the Elastic Curves", by Ralph W. Stewart, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 105.

Columns (2), except that before adding, the top and bottom items are divided by 2 as they apply to only one-half as much length as the others.

To get the position of the center of gravity of the $\frac{M}{t^3}$ - area the moment of each elementary area about Point *B* is computed as shown in Columns (3) still taking the *dl* lengths as unity instead of their real lengths.

The relative distance to the center of gravity of the $\frac{M}{t^3}$ - area is now the summation, Columns (3) divided by the summation of Columns (2); thus (see Table 5): $\frac{112.802}{15.945} = 7.06$. If this actual distance is desired, multiply the relative distance by 3.52, the division length. A similar computation is made for a trial moment of 13 at Point *B* with Point *A* hinged, or by utilizing Maxwell's theorem of reciprocal deflections, the computation for the center of rotation for a moment at *B* can be made with one less column.

It is found that a trial-end moment of 13 at Point *A* gives an $\frac{M}{t^3}$ - area of 15.94 with its center of gravity 7.08 division lengths from Point *B*, and a trial-end moment of 13 at Point *B* gives an $\frac{M}{t^3}$ - area of 16.27 with its center of gravity 7.19 division lengths from Point *A*.

All constants for the beam can now be taken by simple ratio and proportion from the geometry of the traverse diagrams, Fig. 18. These diagrams are similar to the author's Fig. 10 (*a*), except that they are completed to show the centers of rotation which correspond to Point *O* in Fig. 3, or Δ in Fig. 17. Fig. 18 shows a rotation of unity at Point *A*. The other angles are evaluated from the fact that in the traverse triangle the angles are proportional to the opposite sides. The moments appurtenant to the two Δ-angles bear the ratio to the trial moment of 13 that their Δ-angles bear to the $\frac{M}{t^3}$ - area for the trial moment of 13. It is now seen at once that a unit rotation at Point *A* with Point *B* fixed gives

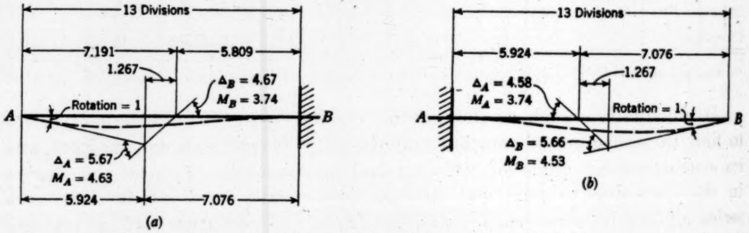

FIG. 18

$M_A = 3.74$, which is the stiffness factor as defined by the author; and a unit rotation at Point B with Point A fixed gives $M_B = 4.53$. These agree with the stiffness factors computed by the author (see, following Table 3). The carry-over factors are also taken off these traverse diagrams by dividing the moment at the fixed end by that at the rotated end.

The saving in computation as compared with Table 2 is more than appears at first glance, because when a slide-rule is set for an $\frac{M}{t^3}$ - value in Table 5[*] it is only necessary to move the runner to the square scale, to extend the computation to Columns (3), since the selection of 13 for the trial moment makes $\frac{M\,x}{t^3} = \frac{M^2}{t^3}$. Taking stiffness and carry-over factors from these traverse diagrams is recommended as being superior to the algebraic solution by means of the Equations (7) to (16), inclusive.

At the end of the paper the author suggests some exercises for any one wishing to acquire proficiency in the geometric treatment of deflections. The last exercise suggested is to devise a method of computing the dead load moments in a two-hinged arch and then find what the dead load moments will be if the structure is transformed into a fixed arch by eliminating the rotation at the base of the two-hinged arch. This problem can be made short and its solution conveniently given in full by selecting, for the arch, a portal frame with level deck and vertical abutments, with uniform moment of inertia throughout, and height = length = L.

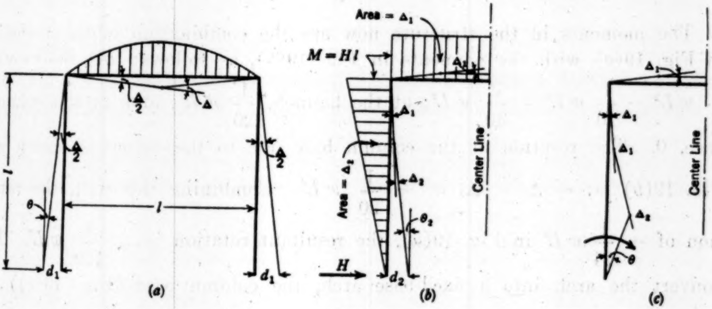

FIG. 19.

In the following solution the Δ-angle points represent centers of geometrical rotation which result from appurtenant sections of the $\frac{M}{EI}$ - diagram. Since E and I (or t^3) are constant throughout, they may be omitted from the computations. For Condition No. 1 (Fig. 19 (*a*)), the arch is taken as a simple structure with no restraint, subjected to a uniform load, w, per unit of length.

---

[*] A complete explanation of the technique of Table 5 may be found in *Bulletin No. 66*, Ohio State Univ., Columbus, Ohio.

The moments are: At the crown, $\frac{1}{8}\ wL^2$; at the haunch, 0; and at the column base, 0. The area of the moment diagram equals,

$$\Sigma M\ dL = \frac{1}{12}\ w\,L^3 = \Delta \ \ldots\ldots\ldots\ldots\ldots\ldots \ (30)$$

The spread at the bottom of the columns equals,

$$2\ d_1 = \Sigma M\ dL\ y = \Delta\ L = \frac{1}{12}\ w\,L^4 \ \ldots\ldots\ldots\ldots\ldots \ (31)$$

and,

$$\theta = \frac{\Delta}{2} = \frac{1}{24}\ w\,L^3 \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots \ (32)$$

For Condition No. 2 (Fig. 19(*b*)), the structure is converted into a two-hinged arch by applying a thrust, H, sufficient to bring the column bases to their original positions: $d = \frac{1}{24}\,w\,L^4 = \Sigma\ M\ dL\ y = \Delta_1\ L + \Delta_2 \left(\frac{2}{3}\ L\right) = \frac{H\,L^3}{3} + \frac{H\,L^3}{3} = \frac{5}{6}\ H\,L^3$. Therefore,

$$H = \frac{1}{20}\ w\ L \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \ (33)$$

The moments in the structure now are the combination of the moment in Fig. 19(*a*) with the moments in Fig. 19(*b*), as follows: At the crown, $\frac{1}{8}\ w\,L^2 - \frac{1}{20}\ w\,L^2 = \frac{3}{40}\ w\,L^2$; at the haunch, $\frac{1}{20}\ w\,L^2$; and, at the column base, 0. The rotation at the column base due to the moments shown on Fig. 19(*b*) is: $-\ \Delta_1 - \Delta_2 = -\ \frac{1}{20}\ w\,L^3$. Combining this with the rotation of $+\ \frac{1}{24}\ w\,L^3$ in Fig. 19(*a*), the resultant rotation is $-\ \frac{1}{120}\,w\,L^3$. To convert the arch into a fixed-base arch, the column base (Fig. 19(*c*)) is made vertical by rotating it through the angle, $\theta = \frac{1}{120}\ w\,L^3$, in a clockwise direction and the resulting moments are determined and combined with those of Fig. 19(*a*) and Fig. 19(*b*). To solve Fig. 19(*c*), a traverse computation is made from the top to the bottom of the column, calling clockwise rotations positive: $-\ 3\Delta_1 - 2\Delta_1 + \Delta_2 = 0$. Therefore, $\Delta_2 = 5\Delta_1$. Summing the angles: $3\Delta_1 = \frac{1}{120}\ w\,L^3$; M (at the haunch) $= \frac{2\ \Delta_1}{L} = \frac{1}{180}\ w\,L^2$; M_2 (at the column base) $= 5\,M_1 = \frac{1}{36}\ w\,L^2$; and the crown moment $=$ the haunch moment $= \frac{1}{180}\ w\,L^2$.

Combining these quantities with the moments in Fig. 19(*a*) and Fig. 19(*b*), the respective moments for the fixed arch are as follows: Crown moment, $\frac{1}{8}\,w\,L^2 - \frac{1}{20}\,w\,L^2 - \frac{1}{180}\,w\,L^2 = \frac{5}{72}\,w\,L^2$; haunch moment, $\frac{1}{20}\,w\,L^2 + \frac{1}{180}\,w\,L^2 = \frac{1}{18}\,w\,L^2$; and, moment at the column base, $\frac{5}{180}\,w\,L^2$.

The foregoing analysis carries the structure progressively, by a geometric treatment of its deflections, through the three conditions of free base, hinged base, and fixed base.

Except for the parts which fail to utilize fully the geometrical properties of flexure (notably the part relating to the constants for a variable section beam), the paper merits attention.

WILLIAM BERTWELL,[9] ASSOC. M. AM. SOC. C. E. (by letter).—Being simple and explicit, this valuable paper is easy to follow. An actual trial of the geometric method should convince most engineers that the usual textbook treatment of many problems (particularly arch analysis) is cumbersome and difficult to remember. The author is to be congratulated for his careful development of the fundamental conceptions as well as for his choice of illustrations.

The virtues of the geometric attack are especially apparent in dealing with trusses, as Mr. Hall shows. Although it is equally convenient to compute the deflections of flexural sections by geometry, in this case the geometric method is also, essentially, the method of elastic weights, since the elastic weight of an element of an elastic rib may be defined as the angular distortion caused by the application of a unit moment couple to that element. Unfortunately, however, the method of elastic weights has come to be completely identified with the conjugate beam convention in the minds of many engineers, and, hence, it may be that the adoption of such a term as "geometric method" is desirable.

For some time the writer has been using the double summation procedure for the calculation of influence lines for the redundants of a fixed arch, and has found this process to be simpler and shorter than any other, unless one uses a definite mathematical arch such as that developed by Charles S. Whitney, M. Am. Soc. C. E.[10] For designers who take rib-shortening into account in arch design, it might be explained that this effect may be included quite simply in the geometric method. For example, in Table 1, the elastic shortenings of the elements are to be computed and the components of these shortenings in the directions of X-X and Y-Y recorded. Then a single summation of the vertical components will provide the corrections to the vertical deflections at the division points, and the total of the horizontal components gives the correction to the horizontal movement of the hinge point.

---

[9] Regional Office, U. S. Bureau of Public Roads, San Francisco, Calif.

[10] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 931.

The author's analysis of the unsymmetrical beam of Fig. 10(*c*) is brief, but the results may be reached with equal facility by adhering to the general method—the mathematical equivalent of the mechanical method. In this case, the analysis may be made by removing one support, fixing the other, and then applying a unit moment and a vertical force at the free end such that the total deflection of that end is zero. The problem is easily visualized in this manner, and one needs no formulas for the evaluation of the constants of the moment-distribution method; it is only necessary to remember their definitions. This process is exemplified in Table 6 by an analysis for one end of the unsymmetrical beam used by the author. (In Table 6, in addition to the notation of the paper, $\Delta = \frac{3.52}{t^3}$; and y = deflection.)

The author's division of the beam into twelve full sections and two half-sections draws attention to a common inaccuracy which can be easily eliminated. Briefly, the correct influence values, found by any process of finite summation, occur only at the divisions between the finite elements—not at their centers. The writer realizes that it is unnecessary to secure extremely accurate results because of the designer's many assumptions, such as the magnitude of the live load and impact forces, the degree of elasticity of reinforced concrete members, and the effect of reinforcing steel in such members. Nevertheless, it is apparent that the results sought are the angular distortion of the element and the deflection of one end from the tangent at the other. The first is the product of the moment and the elastic weight, and the second is the product of the angular distortion and the distance from the instantaneous center of rotation to the face of the element. Hence, one can calculate true deflections only at the division points between the elements. In the graphical solution this means that the true influence curve is tangent to the equilibrium polygon at the division points between the beam elements. Column (11) of Table 6 takes account of this, and it is apparent that the extra labor is slight.

In Column (13), Table 6, are values obtained from an analytical solution of the same beam, taking into account all refinements except shear distortion and the curvature of the top and bottom of the beam between division points. If these values are considered comparatively exact, the error of the writer's approximate solution is only about one-half as great as that which results from using the points at the centers of the elements. The error of the author's solution is small, however, and this may be attributed to his having used rather short divisions of the beam.

It may be well to explain the refinements used in obtaining the "exact" values in Column (13), Table 6. Consider the fundamental elastic properties of a trapezoidal element. It may be shown that the center of gravity of infinitesimal elastic weights is at the intersection of the diagonals, rather than at the mid-point between the parallel bases. Furthermore, the

true elastic weight of the element is measured by the sum of the two parallel bases divided by the square of their product, rather than by the reciprocal of the cube of the depth at the mid-point. For example, if the larger base is 1.25 times the smaller, and the computations are made in the ordinary manner, the error in the location of the elastic center of the element is 5.55% of the length of the element, and the error in the value of the elastic weight is 2.46 per cent. The ratio of 1.25 between the bases is not uncommon, and is slightly exceeded in the author's example. The problem is still further complicated because the instantaneous center of rotation developed in each element by the vertical force at the end is not at the center of gravity of the infinitesimal elastic weights, but at the center of gravity of the infinitesimal angle changes caused by the force. This shift in the center of rotation, when a shear causes the moment in the element (that is, when the moment is not constant throughout the element), is not usually large except for the one or two elements adjacent to the point where the vertical force is applied. In the writer's solution of the author's example, this shift is 0.51 ft for Element *A*-1 and 0.18 ft for Element 1-2. It is a simple matter to use the correct elastic weights, but the variations in their location would indicate that a graphical solution, in which the equilibrium polygon corresponds to the elastic line of the beam, would provide greater accuracy with less labor than the analytical solution. However, an analytical solution taking all these refinements into account is not too lengthy if a computing machine is available. In fact, in this instance only two more operations would have been necessary to include the effect of the shearing distortion.

David B. Hall,[11] Assoc. M. Am. Soc. C. E. (by letter).—In a method of solving problems for which other solutions already exist, it is natural to inquire into the relative advantages of the proposed method. The writer is naturally pleased to observe that those who have discussed the paper have expressed emphatic, favorable views on this question, finding that the proposed method makes the subject of deflections more clearly and easily understood. Mr. McGaw and Professor Grinter, who are both teachers, have especially stressed its value for beginners on this account.

There appears to be some skepticism, however, as to the possibility of this geometrical method taking its place beside some of the older methods for ordinary routine computations, and also for solving difficult problems. It is the writer's feeling that such advantages as the older methods may have are not inherent, but must represent developments with which the newer method has not "caught up." After all, any substitute method depends for its existence upon some mathematical relationship, and however varied its physical interpretations may be, its mathematical operations must be substantially the same. One tool that Professor Grinter mentions, the Williot diagram, in reality, should be classed as one of the most legitimate of the methods of the geometry of deflections.

---

[11] Detailer, Ash-Howard-Needles & Tammen, New York, N. Y.

To make the geometrical method comparable with the older methods as a practical working tool, the greatest need is evidently an accumulation of working details. Several valuable contributions are to be found in the discussions.

Mr. McGaw has begun this filling in by translating the law of reciprocal deflections into geometric terms; and in doing so he has probably made this law more intelligible to many readers. Perhaps it should be noted that one additional step is necessary to develop, fully, a formal proof along this line, because the law of reciprocal deflections applies to any structure in which the materials follow Hooke's law, whereas the foregoing proof is based on relations that exist only in a statically determinate structure. The additional step is merely to trace the effect of adding a redundant support or member to a simple structure.

Specifically, consider three points, *A*, *B*, and *C*, on a simple beam. A redundant support is to be added at Point *B*. When a load is applied at Point *A*, the beam will deflect at Point *B*. If a support is added, the reaction will be proportional to this deflection. Finally, this reaction will produce a deflection at Point *C*. Since, in the simple beam, the reciprocal relation is known to exist between Points *A* and *B*, *B* and *C*, and *A* and *C*, all the factors, multiplied together to find the deflection at Point *C*, due to a load at Point *A*, appear in finding the deflection at Point *A* due to a load at Point *C*. Finally, if the principle applies for a structure with n redundants, the foregoing proof shows it to apply for $(n+1)$ redundants, thus completing the proof by mathematical induction.

A useful geometrical conception, essential to any comprehensive treatment of the subject, is Mr. Stewart's method of traversing the elastic curve. Although it may take a little time to grasp this method fully, the speed and simplicity with which it may be applied to a wide variety of problems make it well worth mastering.

In presenting two alternative solutions for the unsymmetrical beam of Fig. 10(*c*), Mr. Stewart and Mr. Bertwell have illustrated, effectively, the readiness with which solutions may be improvised by these methods—in contrast, for instance, to the necessity for following, faithfully and blindly, some of the older standardized forms for arch computations.

In the second half of his discussion Mr. Bertwell has made a number of observations pertaining to an intriguing branch of mathematics—approximate integration. In its elementary form this is the problem of constructing a polygon to take the place of a curve (as in Fig. 7, for example), and determining the location of the polygon with respect to the curve. In Fig. 7, this polygon consists of a series of tangents to the curve. In such a case Mr. Bertwell's proposal to use interpolated values, which are at the points of tangency of the polygon and curve, is sound. An alternative refinement, used at one time by the writer, was to make corrections at the vertices of the polygon in the same manner that the middle offset of a vertical curve is computed. This correction is $\frac{1}{8}\ \alpha\ dx$. Thus, in Table 1, the correction at Point 10 would be $\frac{1}{8} \times 2.96 \times 4.4 = 1.6$; and the correct deflection would be, $420.6 - 1.6 = 419.0$.

The arrangement in Fig. 10(*c*) and in Tables 2 and 3, however, presents the following entirely different approach, which Mr. Bertwell failed to recognize. If a curve is drawn and marked off at equal intervals, and a polygon is then drawn consisting of a series of chords joining these points, then the angle at any vertex of the polygon will be the product of the curvature in its vicinity and the length of one interval; and the angle between the last chord and the end tangent will be one-half the product of the curvature there and the length of an interval. In this manner the desired results were obtained directly with no extra operations.

It is believed that further refinements, when they are warranted, may be developed more easily in the direction of integration by Simpson's rule, than along the lines described by Mr. Bertwell.

GRAPHICAL DISTRIBUTION OF VERTICAL PRESSURE BENEATH FOUNDATIONS

By DONALD M. BURMISTER,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLIAM P. KIMBALL, I. M. NELIDOV, GEORGE PAASWELL, JACOB FELD, NATHAN M. NEWMARK, A. E. CUMMINGS, D. P. KRYNINE, A. A. EREMIN, AND DONALD M. BURMISTER.

SYNOPSIS

The most important part of the analysis of foundations deals with the settlement of structures due to the consolidation of compressible strata of clay and fine saturated silt located at some depth beneath the structure. This involves the practical application of the theory of elasticity in the determination of the state of stress in the underground. In the present state of knowledge the Boussinesq equation for the pressure at a point within the soil mass, due to a point load concentrated at the surface, is the logical basis for this determination. The practical side of the solution of such problems requires a simplification of procedure, in order to make the valuable method of analysis more available. A method is suggested which makes use of the ideas of the influence line and of graphical integration.

A study of the discussions of foundation problems appearing in recent years makes it seem reasonable to divide them into two general classes. The first class deals with near-surface phenomena, involving the behavior of the soil in the "disturbed zone" close to the individual footings. Bearing capacity is developed by an almost immediate compacting and settling of the soil to a stable condition with some lateral displacement, provided that a certain quite definite loading is not exceeded. The soil may have any moisture content from the dry state to saturation. The second class deals especially with the settlement, over a long period of time, of a structure underlaid by highly compressible saturated layers. The settlement due to the surface phenomena may be negligible compared with the latter.

The essential requisites for such analyses are the determination of the physical properties of the different soil strata and of their behavior under

---

NOTE.—Published in January, 1937, *Proceedings*.

[1] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

load by means of physical tests, and the determination of a fairly complete picture of the distribution of pressure in the underground due to foundation loads. The theoretical aspects of the stress conditions for the surface problems, the points of agreement and disagreement, and the results of investigations have been discussed very completely by Messrs. J. A. Moyer, M. L. Enger, A. T. Goldbeck, W. S. Housel, J. H. Griffith, and A. E. Cummings, Members, Am. Soc. C. E., Dr. F. Kögler, Dr. A. Scheidig, Dr. O. K. Froehlich, and others. Experience has shown that the settlement of full-scale footings is often considerably less and sometimes more than is indicated by extrapolation of small-scale test curves for granular soils. Hence, the important load-area-settlement relations have yet to be completely defined; likewise, the effects of lateral displacement of the soil and of differences of physical properties for full-scale footings are subject to further clarification.

It is well to consider certain questions in order to justify the use of the Boussinesq equation, which represents the only means available for the solution of the second class of foundation problems. The major settlement of structures in this class is due to consolidation of saturated compressible layers, which may be at considerable depth. At a comparatively shallow depth beneath a footing, two to three times its greatest width, the surface loading, due to individual footings, loses its isolated character and merges into a single pressure distribution for the structure as a whole. This occurs below the "disturbed zone" as defined by Kögler and Scheidig. Furthermore, the distribution of the contact pressure, which varies with both the elastic properties of the footing and the soil, becomes unimportant[2].

It is suggested by D. P. Krynine[3], M. Am. Soc. C. E., that the concentration factor, n, in the modified Boussinesq equation[2],

$$p_z = \frac{n\,p}{2\,\pi\,R^2}\left(\frac{z}{R}\right)^n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

is a function of depth, tending toward a value of 3 as depth increases, and that the differences between theory and the results of investigations are merely surface phenomena confined to the disturbed zone. Experience, thus far, seems to indicate that for finer grained soils possessing considerable cohesion and situated at depths at least greater than two to three times the greatest width of the footing, the soil may behave in accordance with the theory of elasticity; and the Boussinesq equation, for which $n = 3$, should give pressures in reasonably close agreement with the actual, if they could be determined in the natural soil.

It would follow from this fact that the principle of superposition of loads may be applied in order to obtain the effect of distributed loads. Glennon Gilboy, Assoc. M. Am. Soc. C. E., has investigated[4] the proper degrees for subdividing a footing into units of such size that the loads on each unit may be considered a point load as assumed in the Boussinesq equation, and has indicated the accuracy that may be attained by such subdivision and superposition of point loads.

---

[2] "Distribution of Stresses Under a Foundation", by A. E. Cummings, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1072.

[3] *Loc. cit.*, p. 1089.

[4] Progress Rept., Special Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., May, 1933, p. 789.

The detailed analysis of the pressure distribution under a large structure becomes exceedingly long and tedious and involves the determination of a complete picture of the state of stress with respect to the compressible layer. The table of Boussinesq coefficients, K, corresponding to values[3] of $\frac{r}{z}$, for determining the vertical intensity of pressure at a point in the underground due to a point load concentrated at the surface in the equation,

$$p_z = \frac{K\,p}{z^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

has placed a useful and valuable tool in the hands of the foundation engineer.

The following method is suggested as a practical simplification of the procedure for determining the stresses beneath a structure. The distribution of vertical pressure on a horizontal plane, mn, at some depth, z, due to a unit point load, p_0, at the surface at Point O, is shown by the typical curve in Fig. 1. The intensity of vertical pressure, p_z, at any point (B, Fig. 1) is given by the ordinate, ab, to the curve at that point. This distribution curve may be used conveniently as an influence line, as suggested by S. Timoshenko[5], for a unit load, p_0 of 1 ton. Then, for a load, P_1, at some point, O_1, the vertical pressure at Point A is given by the product of the ordinate, cd, due to a unit point load directly over A, by the load, P_1. It follows that the pressure, p_z, at Point A for a series of point loads, is given by the sum of the ordinates directly under the point loads, multiplied by p.

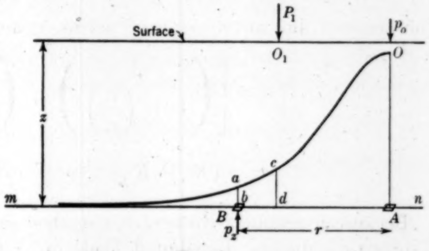

FIG. 1

This idea may be extended to a uniformly distributed line load of p tons per ft, covering all, or any part, of the foundation. The pressure, p_z, at Point A is then given by the area of the distribution curve directly under the loading, multiplied by the uniform loading of p tons per ft.

If this pressure-distribution curve is now revolved about its center at Point A, at which the pressure is to be computed, a bell-shaped surface is formed. Using this area as an influence surface, the pressure, p_z, at Point A is now given by the volume directly under the uniformly loaded area. As the distribution curve is revolved it sweeps out circular segments on the footing area, which are contours of equal pressure. By summing the products of the lengths of each arc by its average pressure intensity and multiplying by the footing load (p tons per sq ft), the total pressure at Point A is obtained. This is simply a graphical method of integration (see Fig. 2), and is the clue to the method proposed herein. The total pressure at Point A due to each

---

[5] "Theory of Elasticity", by S. Timoshenko, Engineering Societies Monographs, p. 88.

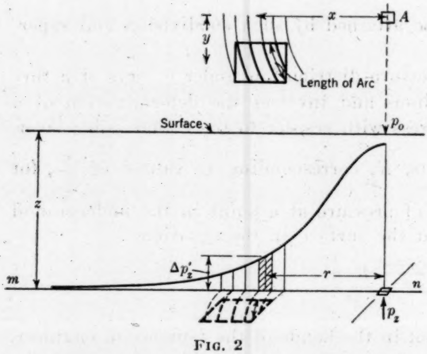

FIG. 2

ring of 1 ft width, is equal to the product of the pressure represented by the shaded area of the distribution curve, having an average ordinate, $\Delta p'_z$, multiplied by $2\pi r$, in which r is measured to the center of gravity of the shaded area. The pressure due to each of these rings may be determined in a very simple manner, because the Boussinesq equation can be readily integrated for circular areas. The pressure at a depth, z, directly under the center of a uniformly loaded circular area of radius, r, is given by,

$$p_z = p\left[1 - \left(\frac{1}{1 + \left(\frac{r}{z}\right)^2}\right)^{\frac{3}{2}}\right] \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The pressure due to any ring of radius, r_1 and r_2, is then,

$$p_z = p\left[\left(\frac{1}{1 + \left(\frac{r_2}{z_1}\right)^2}\right)^{\frac{3}{2}} - \left(\frac{1}{1 + \left(\frac{r_1}{z_1}\right)^2}\right)^{\frac{3}{2}}\right]$$

$$= p\,(K'_2 - K'_1) = p \times \Delta K' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Because a graphical integration method greatly simplifies the computation of pressures due to distributed loads on a foundation, the writer has constructed charts for depths of z = 10, 20, 40, and 80 ft. A sample tabulation

of values of $\Delta K'$, which were computed for the purpose of constructing these charts, is given in Table 1. It is seen from the foregoing discussion that the pressure, Δp_z, at Point A is directly proportional to the percentage of each ring swept out in Fig. 2. Each ring, therefore, is subdivided for interpolation into such unit lengths of arc that the pressure represented is some convenient value as 0.01, 0.02, 0.03 tons per sq ft, etc., and multiples of 10 thereof. The construction of a chart of equal vertical pressure intensities is now very simple. For example, $\Delta K'$ for $z = 10$ ft and a ring of radii of 6 ft and 7 ft, that is, Ring No. 7, is equal to 0.0807 ton per sq ft. The degrees of arc for a pressure intensity of 0.01 ton per sq ft would be, $\frac{360° \times 0.01}{0.0807} = 44.6$. Interpolation is simply in direct proportion to the length of arc. The degree of arc for the pressure intensity of 0.01 for all other rings is obtained from the general equation.

$$\alpha = \frac{360° \times 0.01}{\Delta K'} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

A smooth curve drawn through these points defines the curve for $p_z = 0.01$ ton per sq ft. The curve for $p_z = 0.01$ is one-tenth of the arc for the 0.01 value on each ring. Hence, having constructed the curves for 0.01, 0.001, 0.0001, etc., any degree of subdivision may be obtained by a pair of dividers. The arcs are laid out at the center of each ring which, for all practical purposes, is the center of gravity of the pressure on the ring. Such a chart[6] for $z = 10$ ft and a unit uniform load, p, of 1 ton per sq ft on each ring, is shown in Fig. 3.

The total pressure at Point A due to a uniformly distributed load of 1 ton per sq ft on a footing of any shape, located anywhere within the range of the chart, is now given by the sum of the arc intercepts enclosed on the chart by the footing. The graphical integration is actually accomplished by revolving the footing layout about Point A, so that the reference sides of the footing, *ab* and *cd* (Fig. 3), are brought successively for each ring to the base line, AB, where the arc intercepts can then be readily interpolated. The sum of these intercepts, multiplied by the actual loading in tons per square foot, gives the total pressure due to the footing. The interpolation between pressure curves on the chart is directly proportional to the length of arc intercepted, and is readily made by inspection.

If the point, A, falls within the loaded area, a certain number of complete rings may be contained within the area. The pressure due to these rings is tabulated below the ring numbers. The pressure due to the remaining area is found in this case by interpolating the intercepts as before. The total pressure at Point A due to all the footings within the limits of the chart is obtained by repeating the process for each and summing the effects. This is a simple graphical process and a simple adding machine computation.

The foundation plan is made on tracing paper to the same scale as the horizontal distances on the chart. Each successive point at which the pressure is to be determined in the soil, is pinned down at Point A on the proper chart for depth. If the foundation plan is regular, these points would be most conveniently placed on the center line beneath each footing. The procedure for

---

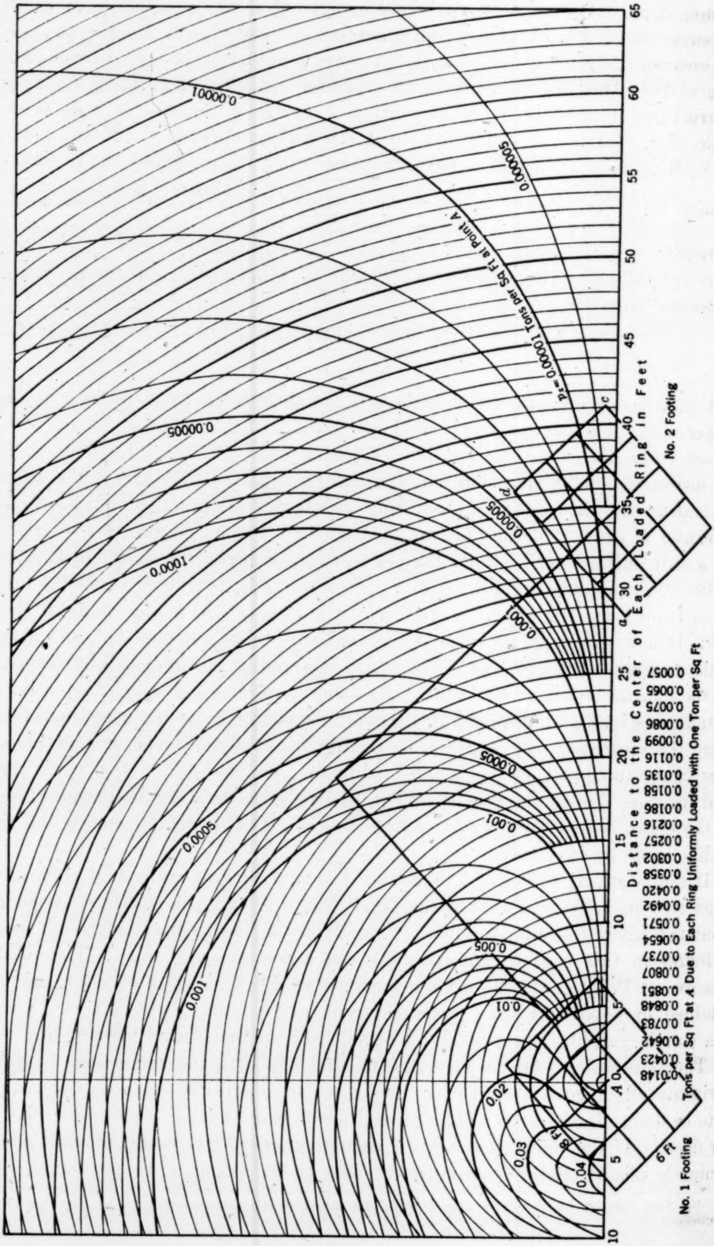

FIG. 3.—PRESSURE CHART FOR z = 10 FEET

the analysis of foundation pressures is indicated in Fig. 4. The pressure at Point *A* due to all footings having an appreciable influence may now be obtained by revolving the foundation plan about Point *A* and summing the effects for each footing, successively. An orderly and logical arrangement of the work will materially facilitate the computation. Most layouts have many

symmetrical arrangements of footings as to location, size, and loading. If these similarities are noted, duplication is avoided and the work is decreased. A sample arrangement of some of the duplicate values to illustrate this problem is given in Table 2. For example, the value obtained for the pressure beneath Footing No. 1 due to pressures exerted by Footing No. 2, when multiplied by 3, takes care of the influence of Footings No. 2, 7, and 19 in the third column. Thus, a set of values indicated by the first and second columns, when completed, serves to fill out the remaining four columns, thus giving the data necessary for determining the distribution of pressure for Section *c-c* at any given elevation, *z*. The sum of all the values found for Footing No. 1 (that is, in the third column complete of Table 2) gives the total pressure beneath Footing No. 1. This value, multiplied by 3 tons per sq ft gives the value which is to be plotted in Fig. 4(*b*). Most of the values in Table 2, with a few additional values, will serve for Sections *a-a* and *b-b*, by noting the symmetry of arrangement.

It can also be readily observed which footings have a negligible effect by noting in what zone it lies on each chart with respect to the center point, *A*, For a depth of $z = 10$ ft, a footing more than 50 ft away produces a negligible pressure because the maximum pressure contours covered equal only 0.00001 ton per sq ft, whereas a footing at Point *A* includes four and one-half full rings of 0.08 maximum pressure. For the example shown footings that are at a greater distance from the one considered (Point *A*), than the following values will not affect materially the third significant figure, which is about the limit of plotting:

Depth, in feet, below the ground surface	Distance, in feet, from any given point
10	50
20	60

* Negligible.

The pressure distribution on a vertical section through Section *c-c* along the center lines of Footings Nos. 1, 2, and 3, is shown in Fig. 4(*b*). It is a simple matter to lay out, by dividers, the distribution of pressure on the horizontal lines, *m-n* and *p-q*, which define the limits of the clay layers. In fact, the pressure at such depths only as are necessary to determine the distribution of pressure within the clay layer, defined by the planed *m-n* and *p-q*, need be determined, as, for example, for $z = 20$, 40, and 80 ft. Similar diagrams may be drawn for Sections *a-a* and *b-b*. The distribution of the pressure on any horizontal plane, such as *m-n* and *p-q*, may then be easily drawn by interpolating contours of equal pressure from curves, such as Fig. 4(*b*), for Sections *a-a*, *b-b*, and *c-c*. These contours have been sketched in in Fig, 4(*a*). The pressures are given in tons per square foot. When the relations between pressure and settlement are obtained from consolidation tests, the pressure contours will define curves of settlement.

Table 4 contains a comparison of values obtained by pressure charts, such as Fig. 3, by the subdivided area method, and by the single, concentrated point load method. The pressures are computed for each footing separately at depths of 10, 20, 40, and 80 ft, along the center line of Footing No. 1 (see Fig. 5).

CONCLUSION

These results show that the point load method is considerably in error, especially close to the footing, whereas the differences between the chart

method and the subdivided area method in general, are small. The saving in time of computation, however, is the important factor. The recent trend toward the use of such labor-saving computing charts in all branches of engineering is indicated by the number of such charts which have appeared from time to time in engineering literature. It is hoped that these charts will prove to be useful and by saving time and labor will make possible a more complete stress analysis in the soil beneath foundations. This would mean that the field of uncertainties would be narrowed down to other considerations and the correlation between the behavior of structures and theoretical and experimental soil mechanics would indicate the necessary modifications and re-adjustments.

The influence-line, graphical integration method may be extended to other problems for which the stress distribution is essential wherever the equation may be integrated for circular areas or by using the method outlined in Fig. 2 and the discussion immediately following.

DISCUSSION

William P. Kimball,[7] Assoc. M. Am. Soc. C. E. (by letter).—As long as the Boussinesq equation is used for the determination of vertical stresses in soil underlying foundations, accurate short-cut methods of applying the equation to actual problems will be of value to the soil engineer. In his paper the author has provided such a tool. The writer has had many occasions to compute, by the Boussinesq equation, the stresses under foundations of various types, and after experimenting with the author's graphical method believes that it represents one of the most efficient time-saving devices available for the solution of most stress-distribution problems.

To illustrate the application of the method the author has shown the analysis of stresses under the centers of individual spread footings supporting a building. A different type of foundation to which the method is equally applicable is a single large area, such as the base of a bridge pier. In this case it is not enough to find the stresses at various elevations under only the center of the area. The net settlement of a bridge pier due to the consolidation of the underlying soil must be caused by the average stresses under the loaded area rather than by the maximum stresses which occur, at least at a distance below the loaded area, under the center of the area. The determination of the average stresses at various elevations under the loaded area

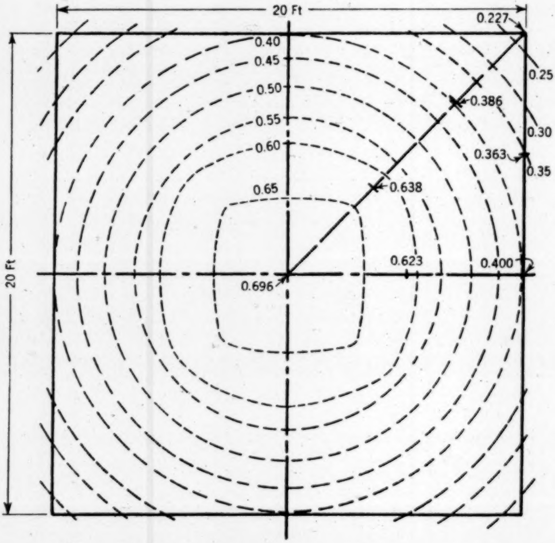

Fig. 6.—Vertical Pressures at $z=10$ Feet Beneath a 20-Foot by 20-Foot Loaded Area

becomes necessary. Using the pressure chart for $z = 10$ ft (Fig. 3) the writer has determined the stresses under various points of a footing, 20 by 20 ft in area, uniformly loaded with 1 ton per sq ft. These stresses, together with the resulting stress contours, are shown in Fig. 6. From these contours it is a simple matter to compute, with satisfactory accuracy, the average stress over the entire area. In this particular instance the average stress was computed to be 0.500 ton per sq ft, as compared with the maximum center stress of 0.696 ton per sq ft. The difference between the stress under the center and the average stress decreases, of course, as the distance below the loaded area increases, and the limit beyond which it is not necessary to compute the average stress can be determined readily by practice.

---

[7] Asst. Prof. of Civ. Eng., Thayer School of Civ. Eng., Dartmouth Coll., Hanover, N. H.

An additional short-cut which may be used in certain cases has been previously suggested[8] by the writer, namely, to compute the stress under the center as under the center of a uniformly loaded equivalent circular area. An equivalent circular area to the 20 by 20-ft square has a diameter of 22.5 ft. Substituting the proper values in Equation (3) of the paper a center stress of 0.707 ton per sq ft is obtained for $z = 10$ ft. This compares favorably with the 0.696 ton per sq ft obtained by the graphical method, and results in a substantial saving of time. The accuracy of this approximation increases, quite apparently, as the distance below the loaded area increases, but decreases as the shape of the loaded area digresses from the circular form. Whether this approximation is sufficiently accurate in any particular case can only be determined from experience.

I. M. Nelidov,[9] Assoc. M. Am. Soc. C. E. (by letter).—Without raising questions as to the distribution of pressure in the upper strata of foundations, the value of the concentration factor, n, and other factors pertinent to the problem of the behavior of soils under load, the writer wishes to apply the principle proposed by the author to the case in which the pressure is not uniform, but varies linearly. In this case the pressure at Point A (Fig. 7), due to a loaded foundation area some distance away, will be:

$$p_z = \sum \left\{ \frac{\Delta K'}{2\pi} \left[p_A \int_{\phi=\alpha_1}^{\phi=\alpha_2} d\phi + r \tan i \left(\int_{\phi=0}^{\phi=\alpha_2} \sin\phi \, d\phi - \int_{\phi=0}^{\phi=\alpha_1} \sin\phi \, d\phi \right) \right] \right\}$$

$$= \sum \left[p_A \frac{\Delta K'}{2\pi} (\alpha_2 - \alpha_1) + \tan i \, \frac{\Delta K'}{2\pi} \left(l_{x2} - l_{x1} \right) \right] = p_{z1} + p_{z2} \ldots (6)$$

in which, in addition to the notation of the paper: p_A is the uniform pressure at Point A, in tons per square foot; p_{z1} and p_{z2} are correspondingly the pressure due to uniform and non-uniform loading; tan i is the slope of the linear variation of the stress taken normally to the line of zero stress due to bending only, in tons per cubic foot (see Fig. 7); and l_{x1} and l_{x2} are the projections of the arc of radius, r, intercepted by the loaded area, on the line, O-X.

---

[8] *Proceedings* Am. Soc. C. E., August, 1933, p. 1060.

[9] Senior Engr. of Hydr. Structure Design, State Dept. of Public Works, Sacramento Calif.

The derivations for obtaining the pressure, p_{z1}, are given by the author. To determine the pressure, p_{z2}, Fig. 8 is constructed similarly to Fig. 3. This is done by taking as abscissas the radii, r, and laying out the distances, l_x, to the left of the point of intersection of the arc corresponding to r, with the line of abscissas, and erecting perpendiculars to the intersection with the arc. The distances, l_x, are selected so as to give even intervals of the load, p_{z2}, with $\tan i = 1$. In this manner,

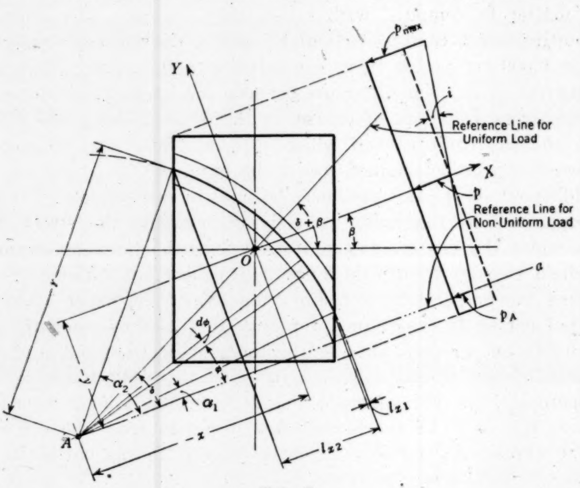

FIG. 7.

$$l_x = p_{z2} \frac{2\pi}{\Delta K'} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

in which p_{z2} is the load, in tons per square foot. For small values of the loads the intersection was determined analytically from the expression, $\cos \Delta = 1 - \frac{l_x}{r}$ in which Δ is the angle between r and the reference line. In order to compute the pressure, p_{z2}, the loaded area is placed on the chart (Fig. 8) so that Line *A-a*, Fig. 7, coincides with the reference line of the chart, and Point *O* is located by the co-ordinates, x and y. Then, positive pressures are read along the arcs intercepted by the periphery of the loaded area. In order to read negative pressures, the footing is rotated 180° about the reference line of the chart, and pressures are read again. These pressures must then be multiplied by $\tan i$ in order to obtain true values of p_{z2}.

For example, consider a rectangular footing 7 ft by 10 ft in area. The uniform pressure is 2.5 tons per sq ft; $\tan i = 0.15$; and the line of zero bending stress is inclined to the axis of symmetry of the footing at an angle, $\beta = 20$ degrees. It is required to find the pressures, p_z, at a point, A, with the co-ordinates, $x = -10$ ft and $y = -5$ ft in the co-ordinate system, XOY (Fig. 7).

The intensity of the uniform pressure at Point A is: $p = 2.5 \times 0.15 \times 5 = 1.75$ tons per sq ft; the total pressure at Point A due to this uniform pressure is obtained with the aid of Fig. 3; and, the angle of inclination of the axis of symmetry of the footing to the base line of the chart, $\beta + \delta$ equals $20 + 27 = 47$ degrees. Consequently, by Equation (6), $p_{z1} = 1.75\ (0.0015 + 0.0025 + 0.0028 + 0.0030 + 0.0029 + 0.0027 + 0.0024 + 0.0022 + 0.0012 + 0.0006 + 0.0003) + (0.0033 + 0.0045 + 0.0048 + 0.0047 + 0.0044 + 0.0041 + 0.0033 + 0.0016 + 0.0008 + 0.0004 + 0.0001) = 1.75 \times 0.0541 = 0.0946$ ton per sq ft.

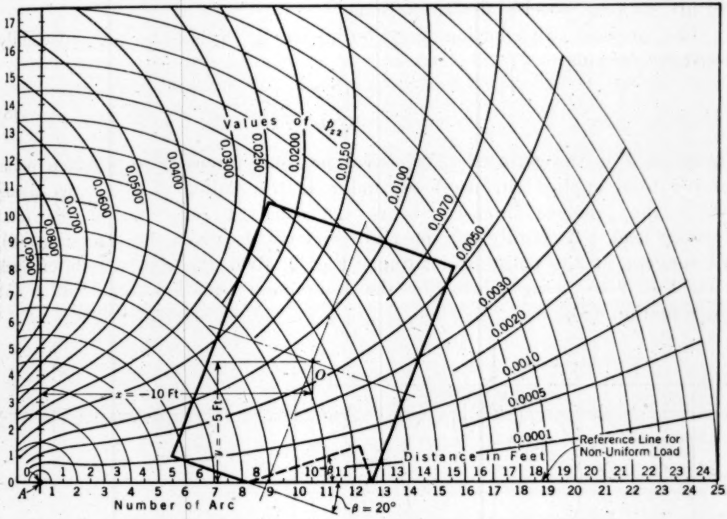

FIG. 8.—CHART FOR DETERMINATION OF VALUES OF p_{z2} WITH TAN $\phi = 1$

The compressed part of the footing is shown in Fig. 8 in full lines, and the tension part is shown in dotted lines. The angle of inclination of the axis of symmetry with the base line of the chart is $\beta = 20$ degrees. The pressure due to non-uniform stresses will be, similarly to p_{z1}: $p_{z2} = 0.15\ (0.0040 - 0.0010) + (0.0100 - 0.0002) + 0.0160 + 0.0205 + 0.0230 + 0.0250 + 0.0250 + (0.0250 - 0.0002) + (0.0230 - 0.0015) + (0.0145 - 0.0029) + (0.0095 - 0.0042) + (0.0066 - 0.0050) - 0.0001 - 0.0001 - 0.0004 - 0.0005 = 0.15\ (0.1741 - 0.0011) = 0.0260$ ton per sq ft. The total pressure will be: $p_z = p_{z1} + p_{z2} = 0.0946 + 0.0260 = 0.1206$ ton per sq ft. If only a uniform pressure of 2.5 tons per sq ft were considered, the pressure at Point A would be: $p_z = p_{z1} = 2.5 \times 0.0541 = 0.1350$ ton per sq ft.

This method may be applied to the computation of pressures caused by continuous non-uniform loadings, such as earth-fill or rock-fill dams, gravity dams, etc. The principle of graphical computation of pressure proposed by the author is practical and labor-saving.

GEORGE PAASWELL,[10] M. AM. SOC. C. E. (by letter).—The recognized importance of determining pressures and their manner of distribution beneath foundations makes it necessary that the formulas covering the determination of such distributions be of ready application. Mr. Burmister's paper is "a step in the right direction." It is realized that the exact determination of the distribution is not necessary; as a matter of fact, present knowledge as to the nature of foundation materials does not yet permit making precise determinations.

The pressure distribution may be given by a simple yet sufficiently accurate formula,

$$r = \frac{0.32}{\sqrt{k}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which k is the ratio of the vertical pressure intensity at a given point to the total applied surface load, and r is the radius of the circle along which the pressure intensity bears the constant ratio, k, to the total surface load. A family of spherical surfaces is given by Equation (8), all tangent at the point of loading. Fig. 9 gives the comparison of such loci, Fig. 9(a) being plotted by the Boussinesq equation, and Fig. 9 (b) by Equation (8).

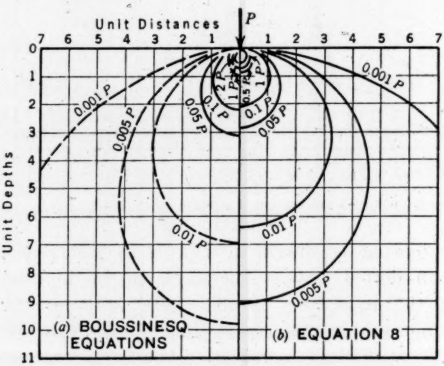

FIG. 9.—LOCI OF CONSTANT VERTICAL PRESSURE INTENSITIES.

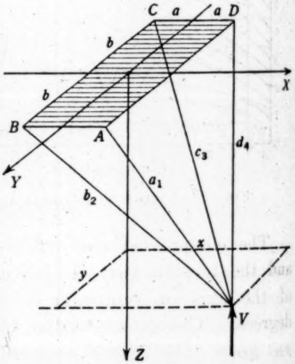

FIG. 10.—DISTRIBUTION OF VERTICAL PRESSURES UNDER UNIFORMLY LOADED RECTANGLE.

The question of the partition of a concentrated load into sufficiently small areas to give correct distribution becomes important at points close to the load. Professor A. E. H. Love has given a solution[11] for the distribution of pressures beneath a rectangle, Fig. 10. The vertical intensity of pressure at a point, x, y, z, with respect to the center of the rectangle as the origin is,

$$V = -\frac{A - z\,B}{2\,\pi}\,p \quad \text{(9)}$$

in which p is the surface load per unit of area. The other terms are as follows (a negative value of V denotes a compressive stress):

$$A = -[2\,\pi - (\phi_1 + \phi_2 + \phi_3 + \phi_4)] \quad \text{(10a)}$$

$$B = (a - x)\,s_1 + (a + x)\,s_2 + (b - y)\,s_3 + (b + y)\,s_4 \quad \text{(10b)}$$

$$\cos\phi_1 = \frac{(a - x)\,(b - y)}{k_1\,k_3} \quad \text{(11a)}$$

$$\cos\phi_2 = \frac{(a - x)\,(b + y)}{k_1\,k_4} \quad \text{(11b)}$$

$$\cos\phi_3 = \frac{(a + x)\,(b - y)}{k_2\,k_3} \quad \text{(11c)}$$

$$\cos\phi_4 = \frac{(a + x)\,(b + y)}{k_2\,k_4} \quad \text{(11d)}$$

$$k^2_1 = (a - x)^2 + z^2 \quad \text{(12a)}$$

$$k^2_3 = (b - y)^2 + z^2 \quad \text{(12b)}$$

$$k^2_2 = (a + x)^2 + z^2 \quad \text{(12c)}$$

$$k^2_4 = (b + y)^2 + z^2 \quad \text{(12d)}$$

$$s_1 = \frac{1}{k^2_1}\left(\frac{b - y}{a_1} + \frac{b + y}{d_4}\right) \quad \text{(13a)}$$

$$s_2 = \frac{1}{k^2_2}\left(\frac{b - y}{b_2} + \frac{b + y}{c_3}\right) \quad \text{(13b)}$$

$$s_3 = \frac{1}{k^2_3}\left(\frac{a - x}{a_1} + \frac{a + x}{b_2}\right) \quad \text{(13c)}$$

$$s_4 = \frac{1}{k^2_4}\left(\frac{a - x}{d_4} + \frac{a + x}{c_3}\right) \quad \text{(13d)}$$

The angles are given in circular measure and may vary from 0 to π. If the fractions are negative (that is, x or y greater than a or b), take the value of the cosine corresponding to the positive value of the fraction and subtract the angle thus found from π. Symbols a_1, b_2, c_3, and d_4 denote the distances from the point to the four corners of the rectangle (see Fig. 10). Equations (9) to (13) fail for points directly under the edges of the rectangle. For such points select points just outside the projections of the rectangle.

It may be interesting to observe how many subdivisions are required, using the Boussinesq formula, to approximate the values as obtained from Equation (9). Select a series of points directly below the center of the rectangle, $x = y = 0$, and assume that $a = 5$; $b = 3$; and $p = 1$. The area of the rectangle is 60 units, and the total load, P, in the Boussinesq formula, is 60.

TABLE 5.—COMPARISON OF VERTICAL PRESSURE INTENSITIES

Values of z	Love	BOUSSINESQ		
		One subdivision	Four subdivisions	Eight subdivisions
1	0.98	28.6	0.01	0.29
2	0.91	7.2	0.42	0.73
3	0.79	3.2	0.61	0.78
4	0.66	1.8	0.62	0.68
5	0.54	1.1	0.60	0.56
10	0.23	0.3	0.23	0.23
20	0.06	0.07	0.07	0.07

Table 5 shows the vertical intensity of the pressure at depths from 1 to 20 as given by Love and by Boussinesq when the rectangle is subdivided into one, four, and eight parts It indicates that a single concentration may be assumed for the rectangular distribution when the point in question is at least 10 ft below the surface.

The writer feels that the method of plane sections[4] as covered in the report of the Committee on Earths and Foundations, is an extremely useful one in considering the effect of a group of pier loads on the deeper strata. A uniform distribution of load may be taken as the equivalent of the various piers and the simple formulas given in the report may be used to determine the vertical loadings at the depths required. The prediction of settlement from an analysis made in this manner will be exact enough in every sense, to make a complete study of the foundation problem.

JACOB FELD,[12] M. AM. SOC. C. E. (by letter).—The graphical interpretation, by Professor Burmister, of the integration of pressure distributions over volumes below the loaded areas is a time-saving tool, which does not reduce the accuracy of the method. However, it is important that one who uses it knows the limitations of the theory and does not expect a result more accurate than can be expected from a tedious analytical computation based on that theory.

---

[12] Cons. Engr., New York, N. Y.

Very properly, the author distinguishes between the problems of "disturbed zone" and deeper layers as an explanation of settlements. The Boussinesq formula, with or without modifications, is only applicable in isotropic bodies. The soils in a "disturbed zone" directly below a foundation are not isotropic. The soils in deeper layers, under initial compression (before the additional loading) are often under such low stresses, that isotropy is closely simulated. Hence, the formula and the author's method are not applicable to the determination of settlements in the "disturbed zone," but can be used for such determinations at greater depths.

The careful reader will notice that the theoretical load distribution is not dependent upon the soil characteristics. This is neither logical nor true. Under low stresses, the error introduced by the assumption that all soils are equal, is so quantitatively small, because the numerical values are small, that it can be disregarded.

Especially in the "disturbed zone" any theory that is based on the assumption that, under equal loading the same distribution will result in mud and in rock, must require modification.

Referring to the numerical example, especially Table 4, and from a general study of the problem of settlements under foundations, one is quite safe in drawing the following conclusions:

(*a*) At depths of 20 ft, or more, the assumption of a single point loading for the usual column footings gives pressure distributions (computed either numerically or graphically) which are as accurate as the computed loadings on such footings.

(*b*) At lesser depths, if the soil is of such nature that isotropic behavior cannot be expected, settlements will occur which cannot be permitted. In this case, loads are transmitted to lower and better layers of soil, by means of piles or caissons.

(*c*) At lesser depths, if the soil is of such nature that isotropic behavior can be expected, settlements are so small that there is no problem.

In all these studies for the estimation of expected settlements, in addition to the nature of the soil, the designer often disregards the effect of the shape of the footings and edge resistance, as well as relative settlements of unequal areas loaded with the same load per unit area. These effects are most important in soils that cannot be assumed to fall in the isotropic group.

NATHAN M. NEWMARK,[13] ASSOC. M. AM. SOC. C. E. (by letter).—The method presented by Mr. Burmister for finding vertical pressures beneath foundations graphically is interesting and simple to use. The author's procedure is more rapid than the method of dividing the loaded area into elements of load which may be replaced by concentrated forces. The writer wishes to supplement Mr. Burmister's method by describing for comparison two other procedures, one analytical and one graphical, which seem to have similar advantages of speed and simplicity.

---

[13] Research Asst. Prof., Civ. Eng., Univ. of Illinois, Urbana, Ill.

An analytical procedure for computing the intensity of vertical stress beneath a loaded area was developed by the writer at the University of Illinois.[14] This procedure makes use of a table of values of vertical pressure at unit depth beneath the corner of a uniformly loaded rectangle of dimensions, *m* by *n*. The table is applicable to all depths and to all dimensions of loaded area. The formula by which the numerical values were computed was obtained by integration over a rectangular area of Boussinesq's formula for the pressure due to a concentrated load. The tabulated coefficients of pressure are given in terms of the vertical load per unit of area on the rectangular area and are dimensionless.

The pressure at points other than under the corner of a rectangular area is found[14] by combining upward and downward loads on not more than four rectangles. For example, the vertical pressure at a depth of 10 ft beneath the center of the footing of dimensions, 6 ft by 8 ft, shown in Fig. 5, is found as the sum of the vertical pressures 10 ft beneath the common corner of four equal rectangles, 3 ft by 4 ft. The "relative dimensions" (*m* and *n*) for these rectangles are 0.3 by 0.4. With these values of *m* and *n*, the table[14] referred to lists a value of influence pressure of 0.04742. Then the influence pressure for the entire footing is four times this value, or 0.18968.

TABLE 6.—INFLUENCE PRESSURES

Depth under center of Footing No. 1, in feet	INFLUENCE PRESSURE DUE TO:	
	Footing No. 1	Footing No. 2
10	0.1897	0.00097
20	0.0542	0.00372
40	0.0141	0.00520
80	0.0035	0.00265

For the problem shown in Fig. 5 of the paper the results given in Table 6 were obtained by this procedure. The writer was unable to make comparisons with the results obtained for the problem of Fig. 4, since no dimensions are given for that problem. Except for pressures near the surface, such a foundation plan can be considered to be replaced by a rectangular area uniformly loaded with the same total load as is applied to the footings. In view of the fact that the computation of pressure in soil is based on assumptions that are only approximately true, such a replacement is permissible. Near the surface, the pressures are affected by the distribution of contact pressure between the footings and the soil, and this distribution may vary between rather wide limits.

It seems that the author's graphical procedure is limited to computations at depths for which charts are available. Only one chart is necessary for all depths if the scale of the foundation plan is changed properly with the depth. For example, Fig. 3, the author's chart for a 10-ft depth, may be used for, say, a 20-ft depth if the scale of distance to the center of each loaded ring is multiplied by 2, so that the rings become 2 ft wide.

---

[14] "Simplified Computation of Vertical Pressures in Elastic Foundations", by Nathan M. Newmark, Univ. of Illinois, Eng. Experiment Station, *Circular No. 24* (1935).

If a graphical procedure is to be used, the writer prefers a pressure chart such as Fig. 11 in which each loaded ring accounts for the same influence pressure. Subdivisions of the rings may then be made by radial lines. The

chart can be made independent of depth by drawing the foundation plan to scale such that the depth at which the pressure is to be computed is taken as the unit of length.

Values of $\frac{r}{z}$ for given values of $\frac{p_z}{p}$ may be computed by re-arranging Equation (3). The writer has made such computations, the results of which are given in Table 7. With these data Fig. 11 may be constructed for the graphical computation of pressure. For the part within the ring marked 0.90, the area between successive circles accounts for an influence pressure of 0.02. Each of the elements of area bounded by the heavy solid lines, outside the ring marked 0.10, accounts for an influence pressure of 0.002, and each of the elements bounded by light lines accounts for an influence pressure of 0.0002. In order to subdivide the area more uniformly, intermediate circles are drawn for the area outside the circle marked 0.90.

The method of using the chart is, as follows: Suppose the depth at which the pressure is desired is 35 ft. Then draw the foundation plan on thin paper or tracing cloth to such a scale that the distance, z, in Fig. 11 represents 35 ft. Set the point at which the pressure is desired at Point A. Add the loaded rings and segments, each multiplied by the value of p on the corresponding area, to obtain p_z; or count the number of blocks or elements of area loaded and multiply by the value of a single block to get the total vertical pressure. A different drawing of the foundation plan is required for each depth investigated, but only the single chart is needed.

A. E. CUMMINGS,[15] M. AM. SOC. C. E. (by letter).—For the calculation of the stress distribution in the ground under a foundation, the author recommends the use of a simple algebraic expression which is often referred to as "the Boussinesq equation." According to Professor Burmister, this equation represents the only means available for the solution of such problems. The writer is of the opinion that the derivation of the equation is based on assumptions which are rarely fulfilled by an actual foundation problem. Accordingly, he proposes to outline briefly the original derivation[16] of the equation and to discuss the assumptions on which it is based.

Boussinesq assumes a rectangular co-ordinate system (Fig. 12), with the XY-plane as the plane horizontal boundary of the semi-infinite solid and with the positive Z-axis directed downward into the solid. He begins with the general differential equations of elastic equilibrium in the form commonly known as the body-shift equations. These are:

$$(\lambda + \mu)\frac{\partial \Delta}{\partial x} + \mu \nabla^2 u = 0 \qquad \text{(14a)}$$

$$(\lambda + \mu)\frac{\partial \Delta}{\partial y} + \mu \nabla^2 v = 0 \qquad \text{(14b)}$$

---

[15] Dist. Mgr., Raymond Concrete Pile Co., Chicago, Ill.

[16] "Application des Potentiels a l'Etude de l'Equilibre et du Mouvement des Solides Elastiques", by J. Boussinesq, Gautier-Villars, Paris, 1885.

and,

$$(\lambda + \mu)\,\frac{\partial \Delta}{\partial z} + \mu \nabla^2 w = 0 \ldots\ldots\ldots\ldots\ldots\ldots (14c)$$

In Equations (14), u, v, and w are the displacements in the X, Y, and Z directions, respectively; and λ and μ are the elastic constants of Lamé, μ being the shear modulus. The cubical dilatation is:

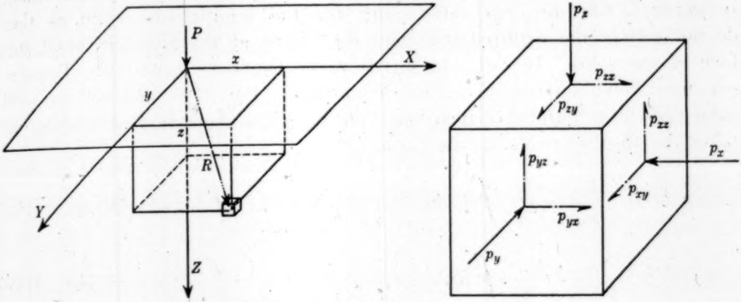

FIG. 12.

$$\Delta = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

and ∇^2 is the Laplacian operator:

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

It is necessary to find expressions for u, v, and w that will satisfy the differential Equations (14) and for this purpose Boussinesq uses certain potential functions. He expresses the displacements in terms of the following:

The inverse or Newtonian potential is:

$$U = \int \frac{dm}{R} \ldots\ldots\ldots\ldots\ldots\ldots (17a)$$

the direct potential is:

$$V = \int R\, dm \ldots\ldots\ldots\ldots\ldots\ldots (17b)$$

the first logarithmic potential of three variables is:

$$\psi = \int \log\,(z + R)\, dm \ldots\ldots\ldots\ldots\ldots\ldots (17c)$$

and the second logarithmic potential of three variables is:

$$\Psi = \int [-R + z \log\,(z + R)]\, dm \ldots\ldots\ldots\ldots\ldots\ldots (17d)$$

In Equations (17), dm is the infinitesimal element of the mass producing the field of force and $R^2 = x^2 + y^2 + z^2$. The integration extends over the mass, m.

By expressing the displacements as the space derivatives of one or the other of these potential functions, Boussinesq finds solutions of the differential Equations (14). These solutions he calls "simple integrals" but, in general, they are not satisfactory for the semi-infinite solid as they do not satisfy the required boundary conditions at the free horizontal surface of the solid. In order to satisfy these boundary conditions, Boussinesq uses combinations of several potentials. For the semi-infinite solid subjected to a purely vertical load on its plane horizontal boundary, he takes the displacements in the form:

$$u = -\frac{1}{4\,\pi\,\mu}\,\frac{\partial^2}{\partial x\,\partial z}\int R\,dm - \frac{1}{4\,\pi\,(\lambda + \mu)}\,\frac{\partial}{\partial x}\int \log\,(z + R)\,dm \quad \text{..(18a)}$$

$$v = -\frac{1}{4\,\pi\,\mu}\,\frac{\partial^2}{\partial y\,\partial z}\int R\,dm - \frac{1}{4\,\pi\,(\lambda + \mu)}\,\frac{\partial}{\partial y}\int \log\,(z + R)\,dm \quad \text{..(18b)}$$

and,

$$w = -\frac{1}{4\,\pi\,\mu}\,\frac{\partial^2}{\partial z^2}\int R\,dm + \frac{2\,\lambda + 3\,\mu}{4\,\pi\,\mu\,(\lambda + \mu)}\,\frac{\partial}{\partial z}\int \log\,(z + R)\,dm \quad \text{..(18c)}$$

Equations (18) are seen to be combinations of the direct potential and the first logarithmic potential, and it is easily shown by differentiation that they are solutions of the differential Equations (14).

To obtain the stresses from the displacements, Boussinesq makes use of the equations of the mathematical theory of elasticity in which the stresses are expressed in terms of the derivatives of the displacements. These are:

$$p_x = -\lambda\,\Delta - 2\,\mu\,\frac{\partial u}{\partial x} \quad \text{........................(19a)}$$

$$p_y = -\lambda\,\Delta - 2\,\mu\,\frac{\partial v}{\partial y} \quad \text{........................(19b)}$$

$$p_z = -\lambda\,\Delta - 2\,\mu\,\frac{\partial w}{\partial z} \quad \text{........................(19c)}$$

$$p_{zx} = p_{xz} = -\mu\left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}\right) \quad \text{..................(19d)}$$

$$p_{zy} = p_{yz} = -\mu\left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}\right) \quad \text{..................(19e)}$$

and,

$$p_{xy} = p_{yx} = -\mu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \quad \text{..................(19f)}$$

In Equations (19), the values of p with the single subscript are the normal stresses and those with the double subscripts are the shears.

If it is assumed that a point load, P, is applied normally to the surface of the solid so that $\int dm = P$, Equations (18) and (19) give the stresses at any point within the solid, as follows:

$$p_x = \frac{P}{2\,\pi}\left\{\frac{3\,z\,x^2}{R^5} + \frac{\mu}{\lambda + \mu}\left[\frac{R^2\,(z + R) - x^2\,(z + 2\,R)}{R^3\,(z + R)^2} - \frac{z}{R^3}\right]\right\} \quad \text{..(20a)}$$

$$p_y = \frac{P}{2\,\pi}\left\{\frac{3\,z\,y^2}{R^5} + \frac{\mu}{\lambda + \mu}\left[\frac{R^2\,(z + R) - y^2\,(z + 2\,R)}{R^3\,(z + R)^2} - \frac{z}{R^3}\right]\right\} \quad \text{..(20b)}$$

$$p_z = \frac{3\,P\,z^3}{2\,\pi\,R^5} \quad \text{......(20c)}$$

$$p_{zx} = \frac{3\,P\,z^2\,x}{2\,\pi\,R^5} \quad \text{......(20d)}$$

$$p_{zy} = \frac{3\,P\,z^2\,y}{2\,\pi\,R^5} \quad \text{......(20e)}$$

and,

$$p_{xy} = \frac{P}{2\,\pi}\left[\frac{3\,x\,y\,z}{R^5} - \frac{\mu}{\lambda + \mu}\,\frac{x\,y\,(z + 2\,R)}{R^3\,(z + R)^2}\right] \quad \text{......(20f)}$$

In these stress equations the plus sign represents compression and the minus sign, tension. Equation (20*c*) is easily recognized as "the Boussinesq equation."

Whether or not Equation (20*c*) is applicable to a given foundation problem depends on how well the foundation problem conforms with the assumptions on which the derivation of the equation is based. As an illustrative example, the author has used a structure built on isolated spread-footings (see Fig. 4). However, there is nothing in the paper to indicate that the charts should not be used for large mat foundations. The assumptions on which Equation(20*c*) is based are more readily understood by consideration of a mat foundation. Furthermore, the author has made several statements which are of considerable interest when applied to a large mat. The writer proposes, therefore, to consider not only Fig. 4, but also the foundation problem illustrated in Fig. 13. This is not an imaginary soil condition. It is more or less typical of certain parts of Chicago, Ill., Detroit, Mich., Toledo, Ohio, and other cities on the Great Lakes.

One important assumption on which Equation (20*c*) is based is that the solid must be homogeneous to an infinite depth. This is required by Equations (18) since the space derivatives of the potential functions in these equations are continuous functions and do not vanish except at infinity. Discontinuities in the soil structure are not compatible with

Equations (18). In Fig. 13, the surface of the bed-rock is at a depth of 90 ft below the ground surface. This rock may be considered as practically rigid so that the vertical displacements must vanish at the plane of the rock surface. The horizontal displacements may or may not vanish, depending on the friction between the rock and the soil stratum just above it. Equation (20*c*) does not apply to this case.

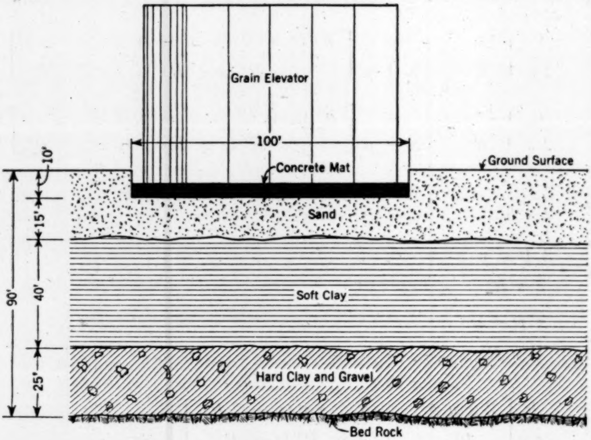

FIG. 13.

A method of taking into account the discontinuity at the rock surface has been published by Professor M. A. Biot.[17] According to Professor Biot's analysis, the vertical normal stress on the center line of the load at the rock surface is considerably greater than the stress calculated with Equation (20*c*). The plane of contact between the sand and the soft clay represents another type of discontinuity. Arthur Casagrande, Assoc. M. Am. Soc. C. E., has studied this condition[18] and has found that a dense sand bed apparently spreads the load so that the vertical normal stresses in the clay are much less than the values given by Equation (20*c*). This question of discontinuities in the soil structure applies to Fig. 4 as well as to Fig. 13. In Fig. 4, it is the width of the entire building that must be considered and not the diameter of the individual footings. Whenever there is bed-rock or some other abrupt change in soil stratification at a depth no greater than one or two times the diameter of the building, Equation (20*c*) does not provide the proper answer.

A second assumption on which Equation (20*c*) is based is that the load must be at the surface of the solid and not below the surface. This requirement is also due to Equations (18). Fig. 13 shows the bottom of the mat at a depth of 10 ft below the surface. This is not an uncommon condition and, in some cases, buildings have several sub-basements so that their foundations are 25 or 30 ft below the surface. Equation (20*c*) is not suitable for such conditions, and it is necessary to use an analysis of the type published in 1936[19] by R. D. Mindlin, Jun. Am. Soc. C. E. Stresses obtained from Mr. Mindlin's equations may vary considerably from those given by Equation (20*c*), depending on the size of the loaded area, its depth below the surface, and the depth of the plane for which the stresses are being calculated.

---

[17] "Effect of Certain Discontinuities on the Pressure Distribution in a Loaded Soil", *Physics*, December, 1935, Vol. 6, p. 367.

[18] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1122.

A third assumption involved in the derivation of Equation (20*c*) is that the load must be normal to the surface of the solid. The displacements represented by Equations (18) are for normal loads only. When the point load, P, is changed to a distributed load, $p\,dx\,dy$, which is to be integrated over a finite area, this normal load requirement does not change, and the load on the finite area must also be purely normal to the surface of the solid. In some cases there is a tendency for the soil to attempt to escape laterally from under the foundation. The condition is similar to that of a compression test on a concrete cylinder in which there are tangential friction forces in the planes of contact between the test blocks and the ends of the cylinder. If the soil attempts to move outward, the friction forces on the soil surface are directed radially inward.

The resultant of the normal load and the friction force at any point makes an angle with the normal, the magnitude of the angle depending on the amount of friction. This oblique resultant force represents a more general case than the purely normal force. For the oblique force the stress distribution within the solid is quite different from that produced by the normal force alone. Boussinesq[20] has solved the problem for the oblique force with the aid of the second logarithmic potential given by Equation (17*d*). Professor O. K. Froehlich[21] has derived equations which show the effect of tangential forces in the contact plane. The existence of this phenomenon has been noticed and discussed[22] by M. L. Enger, M. Am. Soc. C. E. When there are tangential friction forces in the contact plane, the stress distribution in the soil is not that of Equations (20).

The fourth assumption on which Equation (20*c*) is based is that the solid must satisfy Hooke's law and must be a truly elastic isotropic solid in the sense required by the mathematical theory of elasticity. The fact that no elastic constants appear in Equation (20*c*) does not nullify this requirement. The derivation of this formula is based on the differential Equations (14) and these apply only to elastic isotropic solids which satisfy Hooke's law. In order to fulfill these requirements the soil would have to be capable of resisting all tensile, compressive, and shearing stresses represented by Equations (20). Granular soils, for instance, lack the capability of resisting tensile forces except in so far as they may already be under compression due to body forces. At a point on the X-axis at the surface of the solid (in Fig. 12, $z = 0$; $y = 0$; and $x = R$), the shears, p_{zx}, p_{zy}, p_{xy}, and the normal stress, p_z, all vanish. The normal stress p_x, is a radial tension and p_y is a tangential compression. Concentric circles drawn on the surface of the solid, with the origin as a common center, are contracted.

If the physical properties of the soil are such that it cannot resist this tensile stress, p_x, the stress field cannot be represented by Equations (20). Isotropy requires that the elastic properties of the soil would have to be the same in all directions. Stratified silts and varved clays are not isotropic in this sense. Hooke's law requires a linear relationship between stress and strain both for loading and for unloading. In some soils the stress-strain loading curve is a straight line for small strains but in many soils it is not and, in most soils, the process is not reversible. The result is that, in general, it is not valid to consider the soil under a foundation as an elastic isotropic solid. A method of determining the stress distribution in certain types of anisotropic solids has been published by K. Wolf.[33]

The author mentions the "disturbed zone" defined by Kögler and Scheidig and remarks that this region of disturbance extends to a depth of two or three times the greatest width of the footing. Apparently, the author is thinking only of the relatively small spread-footings shown in Fig. 4. The question arises as to how this idea may be applied to Fig. 13. Two or three times the width of this footing means 200 or 300 ft in the ground. It seems scarcely likely that a region of disturbance would extend to any such depth as this. In their original description[34] of this phenomenon, Kögler and Scheidig did not publish any mathematical analysis by means of which the extent of this region could be calculated. However, they called attention to the fact that the depth of the disturbance depended on the physical properties of the soil and the intensity of the surface load. Actually this region of disturbance is a region of plastic flow.

Professor O. K. Froehlich has published[35] equations which define the boundaries between the elastic and the plastic regions. Froehlich's analysis is based on Mohr's theory of plastic flow and his equations include the size of the loaded area, the intensity of the surface load, and the physical characteristics of the soil. In either Fig. 4, or Fig. 13, the extent of this region of plastic flow would depend on these various factors. The region is not merely a function of the diameter of the footing. In addition to this "region of disturbance," Kögler and Scheidig described a "region of no stress" which lies near the surface and surrounds the loaded area. It is in this "region of no stress" that the theory of elasticity, as represented by Equations (20), includes a tensile stress. The inability of sand to resist this tensile stress is part of the cause of the existence of the "region of disturbance."

[35] "Druckverteilung im Baugrunde", p. 72.

The author also discusses the distribution of pressure in the contact plane and states that this becomes unimportant at depths several times the width of the footing. Again, he appears to be thinking only of the small footings of Fig. 4. It is interesting to consider this statement in connection with Fig. 13. As Professor Burmister states, this surface pressure distribution depends on the relative elastic properties of the soil and the structure. It can vary from a distribution which is a maximum at the center and a minimum at the edges to one which is a minimum at the center and a maximum at the edges. In Fig. 13 the entire depth of soil between the bottom of the footing and the surface of the rock is only eight-tenths of the diameter of the footing. It is in this region that the non-uniformity of the surface loading is most important. Even if the rock were not there, and if the soil were a homogeneous, elastic, isotropic solid, the vertical normal stresses on horizontal planes in the region down to an 80-ft depth would be seriously affected by the distribution of pressure in the contact plane. The author's remark about the unimportance of the distribution of contact pressure is apt to be misleading. There are many kinds of foundation problems in which the distribution of pressure in the contact plane cannot be ignored.

The calculation of stress distributions in the ground under a foundation represents the first half of the problem of settlement analysis. The other half is concerned with the laboratory soil tests and the application of the test results to full-sized structures. Many records of observations on the settlements of structures have been published during the past few years. In a few cases there is agreement between prediction and observation, but in many cases there are wide variations. These differences between prediction and observation could result either from the laboratory tests or from the assumed stress distribution in the soil. As far as the stress distribution is concerned, it is the writer's opinion that this so-called "Boussinesq equation" is being somewhat overworked. Foundation problems seldom conform with the assumptions which are the bases of its derivation. Furthermore, the equation is not the only means available for the analysis of stress distributions in the ground under a foundation.

The extent of actual knowledge available at the present time on stress distributions under full-sized structures is extremely limited. The writer, therefore, is inclined to question the desirability of putting into general use such charts as those proposed by the author. These charts are based on an equation taken from the mathematical theory of elasticity, and the equation itself is subject to several definite restrictions. If the assumption is granted that the soil is an elastic, isotropic solid there still remain such questions as: Is the load at the surface or below the surface? Is the load normal to the surface or are there horizontal forces in the contact plane which produce, with the vertical force, an oblique resultant? Is there an unyielding rock stratum or other discontinuity in the soil at a depth no greater than one or two times the diameter of the structure? The author's charts do not take any of these conditions into account.

If it is admitted that the soil is not an elastic, isotropic solid, it becomes necessary to abandon the use of the theory of elasticity altogether, or at least to modify the equations of that theory before they are used to calculate stress distributions in soils. Apparently, it is true that, at considerable depths below the surface, the materials of the earth behave approximately as elastic, isotropic solids. Much of the science of seismology is based on this assumption.[26] However, it is the writer's opinion that most foundation problems are concerned with surface phenomena. In general, the entire depth of soil involved in the problem is of the same order of magnitude as the diameter of the structure, and there are usually a number of other special conditions to be considered. It would seem better, therefore, to leave the door open to a consideration of these special conditions rather than to advocate the use of charts which do not take them into account at all. In any case, the charts and tables should be supplemented by a complete statement of the assumptions on which they are based so that the user may be fully aware of their limitations.

D. P. Krynine,[27] M. Am. Soc. C. E. (by letter).—The object of this discussion is: First, to emphasize the outstanding place which the chart method advanced by Professor Burmister occupies among other methods of determining the vertical pressure within a loaded earth mass; and, second, to suggest some further simplifications of the method in question.

Existing Methods of Determining Vertical Pressure Within a Loaded Earth Mass.—The problem of determining the vertical pressure, p_z, at a point within an earth mass as caused by a structure at the top (horizontal boundary plane) of that mass, has been solved, to date, in four different ways: (1) Subdividing the loaded area at the base of the structure into small rectangles and replacing each of them with an equivalent concentrated load acting at the center of the rectangle in question; (2) subdividing the loaded area by arcs of circles and their radii into small elements, and replacing the latter with equivalent concentrated loads; (3) developing theoretical (so-called "strict") formulas to express the pressure, p_z, caused by a rectangular or circular loaded area; and (4) compiling tables and tracing graphs. In practically all existing methods the validity of the Boussinesq formula is an assumption; in other words, the earth mass is considered to be an elastically isotropic body. Furthermore, only uniform load distribution through the loaded area is considered, with a few exceptions, mentioned subsequently. The writer has also proposed a method of determining the vertical pressure, p_z, within any earth mass and under uniformly or non-uniformly loaded structures of an arbitrary shape.[28]

[27] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

[28] *Transactions*, Am. Soc. C. E., Vol. 103 (1938).

For the purposes of this discussion, however, the writer's method will be left entirely out of consideration.

A characteristic representative of the methods corresponding to Item (1) is that proposed by Glennon Gilboy, Assoc. M. Am. Soc. C. E.,[29] in 1933. This method is the one most used by soil mechanics investigators in the United States. It yields quite satisfactory results in the case of uniformly loaded areas composed of one or more rectangles. A semi-graphical method elaborated by Messrs. Kögler and Scheidig,[30] of Germany, corresponds to Item (2). This method may be applied to both uniformly and non-uniformly loaded areas. Owing to certain assumptions the method furnishes approximate results. The group under Item (3) is the most numerous. The stressed condition beneath circular and rectangular uniformly and non-uniformly loaded areas has been studied by various investigators, and pressures have been found mostly at points along the vertical center line of a circle or of a rectangle, as well as under a corner of a rectangle. In this respect, works of Boussinesq, Love,[31] and other theoreticians in the field of elasticity, are to be mentioned (also those of Professor F. Schleicher,[32] of Germany, Dr. O. K. Fröhlich,[33] of Holland, and Professor F. E. Relton,[34] of Egypt). A. E. Cummings,[35] M. Am. Soc. C. E., has studied, in a comprehensive manner, a considerable number of cases of uniformly and non-uniformly loaded circular areas and has developed formulas to compute pressures at points along the vertical center line. Since the methods corresponding to Item (3) are applicable only in the case of regular, circular, or rectangular areas, they have, as a rule, only a restricted value.

So far as the writer is aware, there are two works to be classified under Item (4): That of Nathan M. Newmark, Jun. Am. Soc. C. E.,[36] and that of Dr. Wilhelm Steinbrenner,[37] of Austria. Both these investigators studied the case of uniformly loaded rectangles and computed pressures at the corner; Mr. Newmark has compiled comprehensive tables and Dr. Steinbrenner has traced ingenious graphics which permit the computation not only of the pressure, p_z, but also of the value of the elastic settlement at the corner of a uniformly loaded rectangle. Although the methods of this group refer to rectangular loaded areas only, their particular value consists in their tendency to facilitate the work of the designer, placing in his hands such time-saving devices as tables and graphs.

Chart Method Discussed.—The work of Professor Burmister belongs to Group (4); but it is more applicable to actual engineering computations than the work of Dr. Steinbrenner which is the closest to it as far as the method of attack is concerned. This is because Professor Burmister's method can be used in the case of a uniformly loaded structure of an arbitrary shape. His graphs permit the taking of readings at every foot, or, if desired, more closely, thus approaching the continuity of load distribution. The writer cannot qualify the work of Professor Burmister otherwise than as a correct step in the right direction; but, at the same time, he wishes to emphasize a few features of this method which should be improved, at least partly.

The fact that, in this method, the earth mass is considered only as an elastically isotropic body, cannot be considered as a weakness of the method since the theory of the concentration factor has not been generally adopted as yet by all soil mechanics investigators; and yet it has been felt that at greater depths the Boussinesq formula holds. The method in question, however, involves some less important disadvantages of a purely practical character; (*a*) The given structure or set of footings must be re-drawn on transparent paper to the scale of the diagram (Fig. 3), and this means a certain loss of time; and (*b*), the pressures can be determined only for the depths, for which charts have been prepared. It is true that for intermediate values the pressures can be determined by interpolation; but to use the interpolation method, at least three pressures at three different depths must be found first, before it is possible to trace a curve. Two pressures would give only a straight line and a rough interpolation.

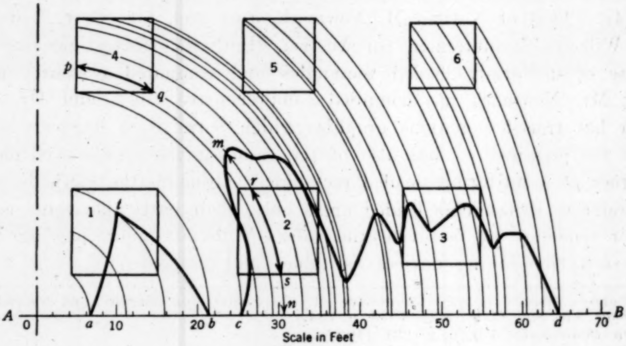

FIG. 14.

A Simplification Suggested.—Furthermore, Professor Burmister suggests that the re-drawn plan of the structure be pinned down at Point *A*, Fig. 3, and that the plan be revolved for making readings. This procedure may be substantially simplified as follows: (*a*) Charts are prepared on tracing cloth; and (*b*), the plan of the structure is drawn on ordinary paper to the scale of the chart. Fig. 14 represents the first quarter of the foundation layout in Fig. 4. If the vertical pressure is to be determined at some depth under Point *A*, all the footings should be referred to an arbitrary line, *AB*, passing through Point *A*, as follows: With Point *A* as a center, arcs are drawn through all breaks in the plans of the footings. Distances of each arc intersecting footings are added, using dividers to measure chords; for this purpose, these distances are plotted along each corresponding arc, starting from the point of intersection of that arc with Line *AB*. For instance, Segments *pq* (Footing No. 4) and *rs* (Footing No. 2), when plotted upward from Line *AB*, Fig. 14, are represented in Segment *mn*, the length of the latter being equal to the sum, $\overline{pq} + \overline{rs}$. Joining all points such as *m*, Areas *atb* and *cmd* would be obtained bounded at the bottom by the straight line, *AB*, and at the top by the irregular curves shown in Fig. 14. The vertical pressure, p_z, produced by the loaded areas, *atb* and *cmd*, at a particular point of the earth mass located at the vertical passing through Point *A*, equals that produced at that particular point by Footings Nos. 1, 2, 3, 4, 5, and 6. To measure this pressure, the transparent chart is simply placed over the layout of the foundation, making Points *A* of both drawings coincide (see Figs. 3 and 14); and Line *AB* of the layout (Fig. 14) is made to coincide with the basic horizontal line at the bottom of the chart (Fig. 3). Then readings are made along the upper boundary curve, of Areas *atb* and *cmd*.

The writer has made a comparative computation using both Professor Burmister's chart method and the suggested simplification. The saving in time obtained in the latter case can be estimated at least at 25 per cent. The more numerous the footings (or the buildings in the case of a built-up area), the more considerable will be the time saved. Such a feature of the chart method as Table 2 should be abandoned if this simplification is used. Moreover, it would be no longer necessary to pin the graph at Point *A* and rotate the plans.

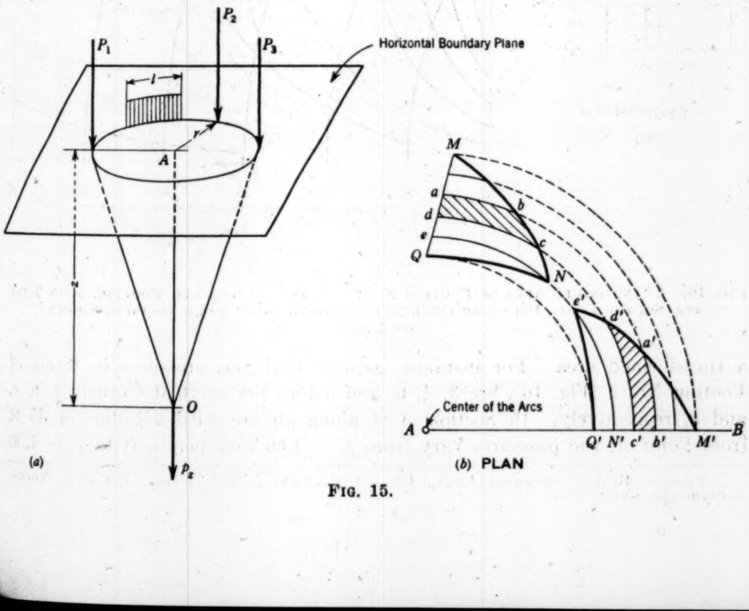

FIG. 15.

Theoretical Basis of the Simplification.—The theory underlying the suggested simplification, may be deduced from Fig. 15. In both Fig. 14 and Fig. 15, Point *A* is the projection on the horizontal boundary plane of Point *O*, at which the vertical pressure, p_z, is to be determined. Loads $P_1 = P_2 = P_3$, acting at different points of a circumference for which Point *A* is the center, produce equal vertical pressures, p_z, at Point *O* (Fig. 15(*a*)). This is because the values, *r* and *z*, influencing the vertical pressure, p_z, at Point *O*, are constant for all points along that circumference. In an analogous manner, a line load of a certain intensity and of a length, *l* (Fig. 15(*a*)), acting along a part of the circumference under consideration, may be moved to any other place on the same circumference without influencing the vertical pressure, p_z, at Point *O*. Furthermore, a loaded strip, *abcd* (Fig. 15(*b*)), may be transferred to Line *AB*, in the form of the strip, *a′b′c′d′*. The entire area, *MNQ*, if referred to Line *AB*, would be represented by the area, *Q′e′M′*. The construction used in Fig. 14 is based on the same idea.

A. A. Eremin,[38] Assoc. M. Am. Soc. C. E. (by letter).—An interesting method of computing foundation stresses by means of the Boussinesq equation, is contained in this paper. Mr. Burmister has applied his method to footings with uniform pressures. However, Fig. 3 may also be used in computing foundation stresses beneath footings with non-uniform pressure distribution. The areas of such footings should be expressed in terms of a transformed area. For instance, assume that the pressures in terms of Footing No. 2 (Fig. 16), are 3, 4, 6, and 5 tons per sq ft at Corners *a*, *b*, *c*, and *d*, respectively. In Section *A–A* along an arc with a radius of 35 ft from Point *A*, the pressures vary from $p_1 = 4.66$ tons per sq ft to $p_2 = 4.50$

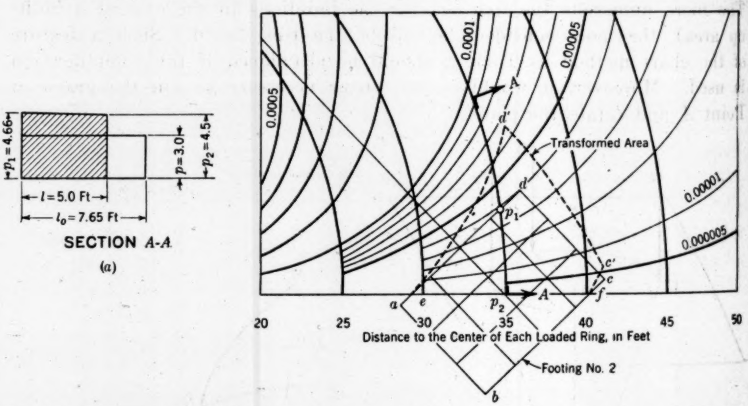

Fig. 16.—Transformed Area of Footing No. 2. Pressure Beneath Footing, *p*, in Tons per Square Foot; Pressure Chart and Footing No. 2 Same as That Shown on Fig. 3.

---

[38] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

tons per sq ft (see Fig. 16(*a*)). By changing the length, l, the area of the pressure diagram may be expressed as an equivalent area of uniform pressure. The length, l_0, of the footing in Section *A–A*, Fig. 16(*a*), with a uniform pressure of $p = 3$ tons per sq ft, is,

$$l_0 = \frac{(p_1 + p_2)\, l}{2p} \quad \text{.......................} (21)$$

or, $l_0 = \frac{(4.66 + 4.50)\, 5}{2 \times 3.0} = 7.65$ ft.

The width of the transformed area may be constructed along the arcs at various distances from Point *A*. The computed area of the footing, with a uniform pressure of $p = 3$ tons per sq ft, is shown in Fig. 16 by dotted lines, *e*, *d'*, *c'*, and *f*. Area *abfe* (Fig. 16) is revolved 180° about Line *ef* and is also converted or transformed into an equivalent uniform pressure. Foundation stresses beneath this transformed area may be computed as shown by the author in Fig. 3.

If the pressure curves under the footings are irregular, the area of the pressure diagram along the arcs may be determined by planimeter measurements, or by approximate summation. The width of the transformed footing along an arc, l_0, will be,

$$l_0 = \frac{A_p}{p} \quad \text{.........................} (22)$$

in which A_p is the area of the pressure diagram, and p is the assumed uniform foundation pressure. For convenience of computations the uniform foundation pressure may be assumed to be the same as the average footing pressure.

The method presented by Mr. Burmister saves time in computing foundation stresses beneath multiple footings. Most of the labor involved in his method is that required in preparing the charts for pressures in planes at various depths, and the author, therefore, should be encouraged to present his complete set for practical use in design problems. Without such charts, if the pressures considered are produced by a single footing, foundation stresses could be determined in less time by the graphical method developed by D. P. Krynine, M. Am. Soc. C. E.,[28] in which construction of pressure charts is not required.

DONALD M. BURMISTER,[39] ASSOC. M. AM. SOC. C. E. (by letter).—The constructive nature of the discussions is gratifying, and the writer feels that the value of the paper has been materially increased thereby. The comments have revealed interesting practical uses, and have suggested valuable "short-cut" procedures.

Although it was not the intent of the writer to go into the limitations of the Boussinesq theory, it is of the greatest importance to have a clear understanding of the situation in any given case. Mr. Cummings has given an excellent discussion of how well the foundation problem conforms with the assumptions on which the Boussinesq theory is based, and

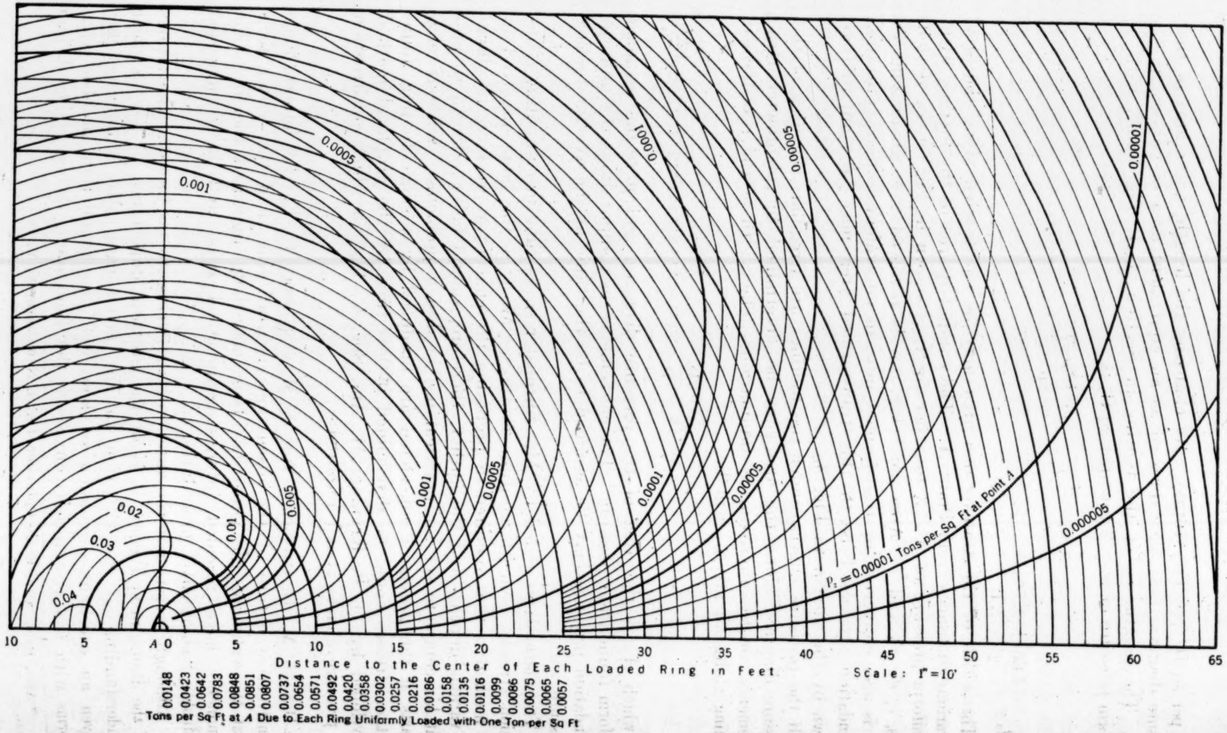

FIG. 17.—PRESSURE CHART FOR $s = 10$ FEET.

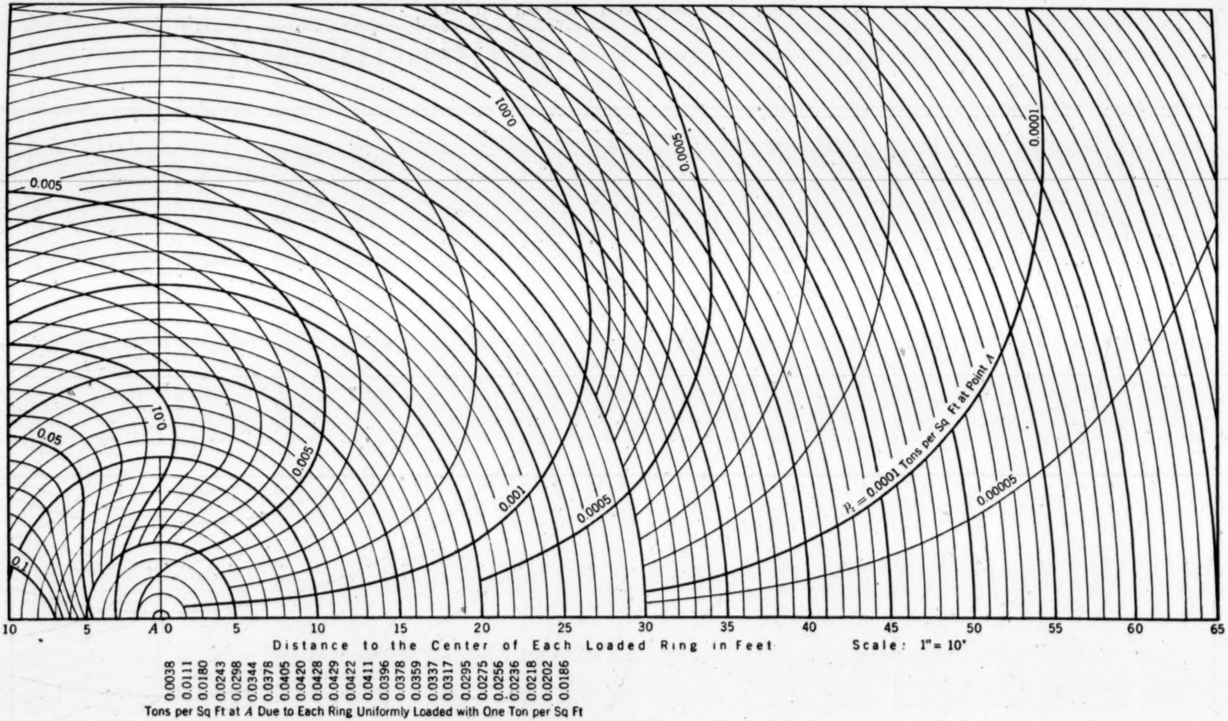

FIG. 18.—PRESSURE CHART FOR $z = 20$ FEET.

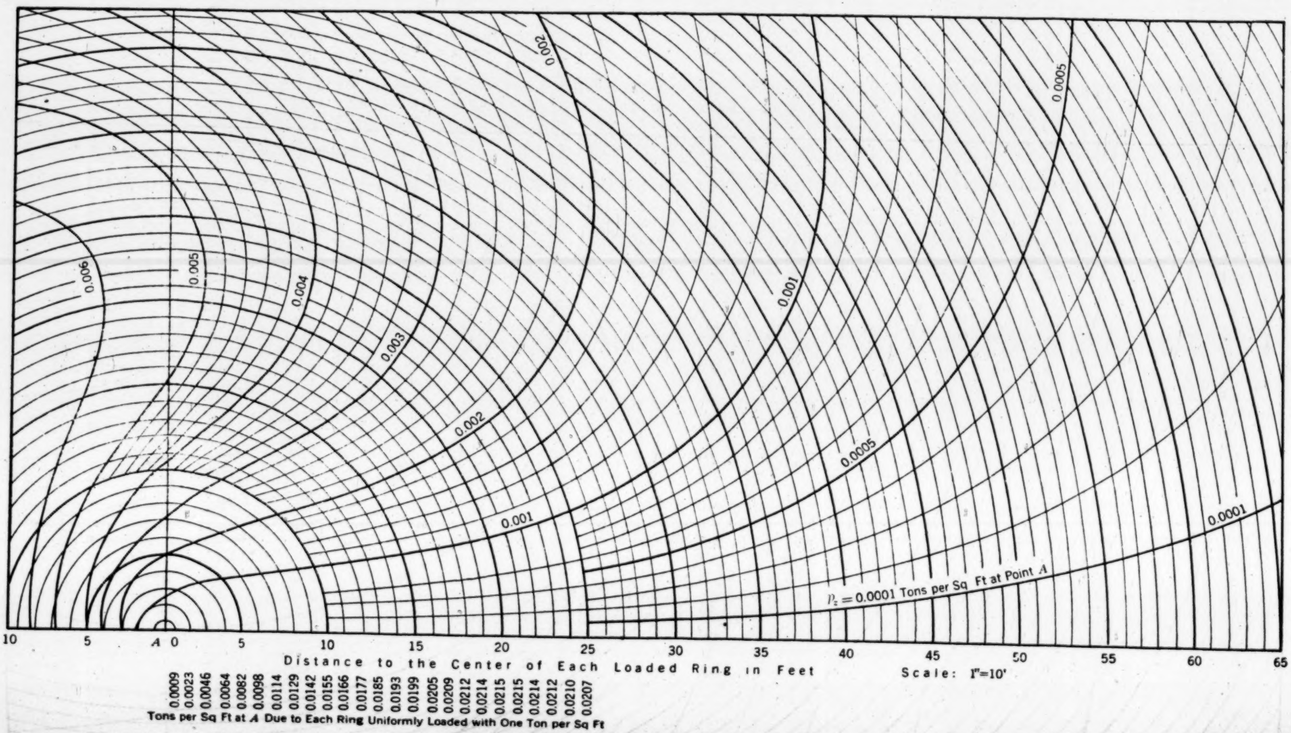

FIG. 19.—PRESSURE CHART FOR $z = 40$ FEET.

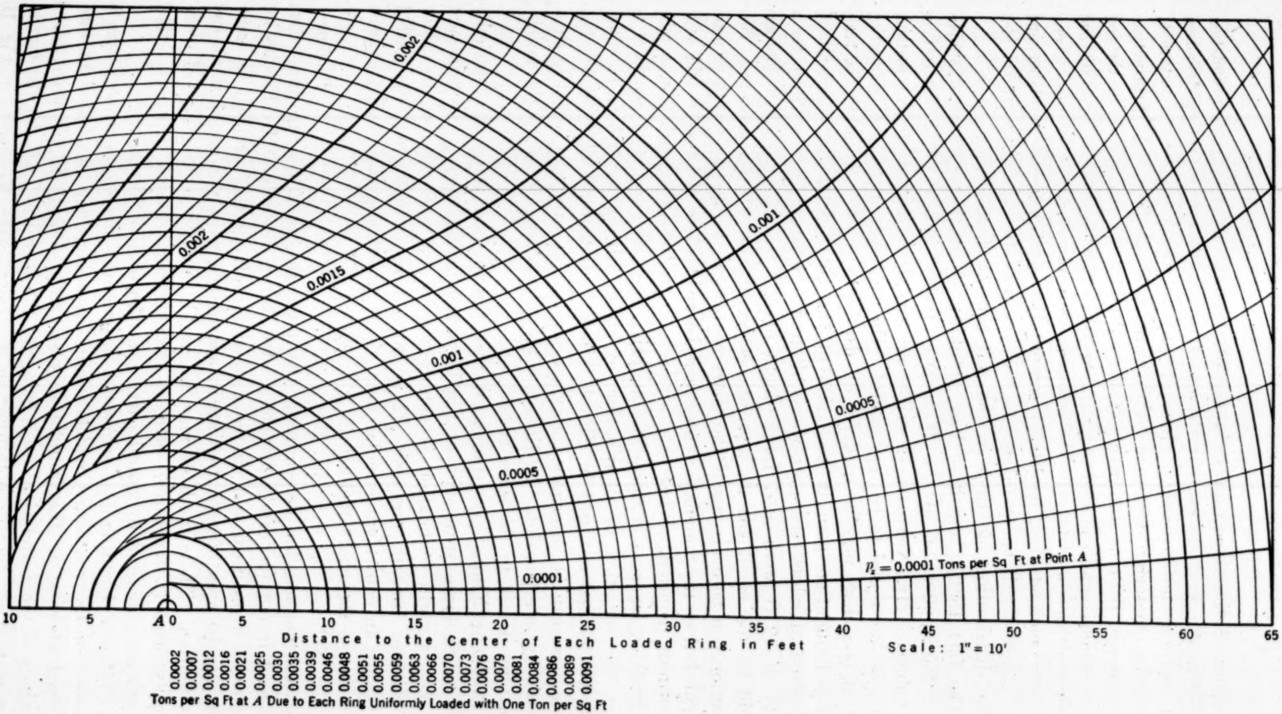

FIG. 20.—PRESSURE CHART FOR $z = 80$ FEET.

has outlined the important influence of discontinuities in the foundation soil. Mr. Paaswell shows that the exact determination of the distribution of pressure is not necessary, since present knowledge as to the nature of foundation material does not yet permit making precise determination. For example, little is known about the actual stress conditions in the soil under various conditions of loading, or the influence of stratification and discontinuities upon the way the stress is transmitted into the soil. Therefore, any method that facilitates computation and reduces the labor and time involved will be useful to the soil engineer in obtaining a good idea of the distribution of stress in the soil beneath foundations.

The fact that others have been thinking about the problem of simplifying the application of the Boussinesq theory indicates the interest in the subject. Mr. Newmark describes an analytical and graphical method, which he has found to be very useful. He has made a valuable suggestion in that one chart may be used for all depths by simply changing the scale of the foundation plan in the ratio of the chart depth to the depth of the plane at which the pressure is desired. However, if the chart for a depth of 10 ft were used for a depth of 100 ft, the individual footings would be too small for an accurate determination of the pressure. This objection can be overcome if the chart nearest to the desired depth is used, provided that the foundation plan can be reduced easily to the odd scale sometimes required. Where the stresses are to be investigated in a relatively thick layer of compressible material, such as clay, it is necessary to know the variation or distribution of stress within the layer, in which case the method outlined in Fig. 4 is most satisfactory. The distribution of pressure can be determined at three levels, obtaining the complete stress picture by interpolation. In this case the charts are used with the foundation plan drawn to the same scale.

Professor Kimball has indicated that the method is equally applicable to a single large area, such as the base of a bridge pier. The settlement of such a rigid foundation is determined by the average pressure acting in the soil beneath the pier. It is interesting to note that the method of taking an equivalent circular area yields practically the same maximum pressure as the chart method.

Mr. Nelidov has extended the usefulness of the charts by developing a practical method for determining the pressure beneath a footing, where the load is not uniformly distributed but varies linearly. Mr. Eremin has suggested a practical and simple method of solving this problem by transforming the area of each footing in accordance with the non-uniform load distribution. These methods may be readily applied to the case of eccentrically loaded structures, such as eccentrically loaded footings, bridge abutments subjected to lateral earth pressure of the fill, etc.

Professor Krynine has suggested a practical improvement and simplification in the procedure, which results in a considerable saving of time. Instead of rotating the foundation plan about Point *A*, the areas of all footings of the foundation are referred to the base line, *AB*, on the foundation plan itself, thereby obtaining an equivalent area, as shown in Fig. 14.

The base line, AB, of the footing plan is made to coincide with that of each chart in turn, and the readings to the boundary curve of the equivalent area are then added to obtain the total pressure of all footings at the point under consideration. Fig. 3, for $z = 10$ ft, was submitted as a specimen to demonstrate the type of chart recommended.

Figs. 17 to 20 are pressure charts corresponding to Fig. 3, designed for use in actual practice. The scale reduction has been adjusted purposely to 1 in. = 10 ft.

RAINFALL INTENSITIES AND FREQUENCIES

By A. J. Schafmayer[1], M. Am. Soc. C. E., and B. E. Grant[2], Esq.

With Discussion by Messrs. Victor H. Cochrane, LeRoy K. Sherman, J. O. Jones, Charles W. Sherman, Glen N. Cox, Garrett B. Drummond, Eugene L. Grant, Adolph F. Meyer, Clinton L. Bogert, C. H. Eiffert, C. S. Jarvis, and A. J. Schafmayer.

Synopsis

An investigation of the relation of frequency to rainfall intensity, by the statistical method, forms the basis of this paper. All the available records of excessive rainfall published by the United States Weather Bureau for nineteen cities were first examined and those exceeding certain rates were tabulated and plotted on semi-logarithmic paper. The graphs were straight lines of marked regularity in their arrangement. Then, the data from ten cities of the original nineteen were tabulated and plotted, thus using about one-half the quantity of data first used. A similar regularity and consistency in the curves were found. Finally, the data from fourteen rain-gages in the Chicago (Ill.) District were used for finding curves and formulas for the use of the City of Chicago. The formulas for intensity are rectangular hyperbolas and are plotted on hyperbolic paper as straight lines. The study is limited to excessive storms having durations of 120 min, and less.

Introduction

Rainfall intensity is involved in the design of storm sewers, as the rate of run-off is generally a function of the intensity. Adequate knowledge of intensities only becomes available with the accumulation of long-time records of automatic recording rain-gages. As the automatic gage has been in general use for only a few decades, formulas for intensity derived in the early part of the Twentieth Century were based on scanty information and should be revised.

The Board of Local Improvements of Chicago, a department of the Municipal Government which designs and builds most of the City's sewers, has

---

Note.—Published in February, 1937, *Proceedings*.

[1] Engr., Board of Local Impvts., City of Chicago, Chicago, Ill.

[2] Div. Engr., Board of Local Impvts., City of Chicago, Chicago, Ill. Mr. Grant died on October 30, 1936.

been using a formula for rainfall intensity of the exponential type which was adopted in 1915. It was based on the rather scant information about the rainfall of Chicago available at that time. (The Sanitary District of Chicago, a separate and independent municipality, builds and maintains intercepting sewers which carry the dry-weather flow of the sewers of Chicago and other cities to treatment plants. Its sewers, not being owned or controlled by the City of Chicago, are not classed herein as city sewers.)

The multiplication of gages in recent years and the corresponding increase in the available data have led to a more complete study of rainfall intensities and frequencies by the Board than had previously been made, and to the search for formulas that would be the basis for more rational and economical design.

The study included the determination of a method for using data from a number of gages and an investigation of the validity of the station-year method for utilizing such data. Some of the results of that study are presented herewith in an abridged form.

The hyperbolic type of formula for intensity of rainfall, originated about forty years ago by A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., has been found to fit the data more consistently than the exponential type. This study includes only storms of 2-hr duration and less, and the formulas are not intended for longer durations. However, this time is sufficient for the majority of cases in the design of city sewers.

In order to obtain a sufficient quantity of data on excessive storms, the records of a number of rain-gages in different cities are combined. These records give consistent and characteristic curves which afford a basis for judging the sufficiency of the lesser number of records which are available in a single city.

The rainfall at any given point results from the operation of a number of unknown laws. It is classified, therefore, as a chance event. If rainfalls of certain intensities and frequencies do follow a law within limits, the question arises as to how many data are needed to determine such law. The record from a single rain-gage for 100 yr is much more valuable than the record from the same gage for 25 yr, or even for 50 yr.

The tipping-bucket gage of the U. S. Weather Bureau which gives short-time records of excessive storms has not been in use long enough to give the desired quantity of data, and, therefore, some method must be used which will give reasonable results with scanty data.

The method of approach used in this paper accepts and classifies the available authentic data of a region or an area having somewhat similar rainfall characteristics and thus accumulates a number of observations great enough to indicate a rule or a law.

DEFINITIONS OF TERMS

The following definitions, abbreviations, and letter symbols apply thoroughout this paper:

"Intensity", i, is the rate of rainfall, in inches per hour.

"Duration", t, is the elapsed time, in minutes, for the excessive rainfall.

"Quantity of precipitation", d_a, is the total rainfall, in inches, for the time given.

"Frequency", F, is the average time, in years, between occurrences.

"Station-years" for a number of stations is the sum of the years of record for all stations in the group.

"Excessive rainfalls" are those equal to or greater than the smallest quantities used in the tabulations. These quantities are:

Rainfall, in inches	Duration, in minutes	Rainfall, in inches	Duration, in minutes
0.35	5	1.20	60
0.50	10	1.30	100
0.65	15	1.40	120
0.90	30		

"Chance event", is one in which the determining factors are unknown or are so complex that the result can be predicted only as an average, if at all.

DEFICIENCIES IN DATA

When one attempts to find an expression for intensity of rainfall for any given frequency for Chicago, several difficulties appear:

(*a*) The record of excessive storms is a comparatively short one.

(*b*) The number of gages having an available record is too small.

(*c*) The published records give the quantity of rainfall for successive 5-min intervals, and it is only by chance that these may correspond to maximum quantities for short durations.

(*d*) The type of gage in use does not make a correct record of high intensities of short duration.

(*e*) The published summaries of the U. S. Weather Bureau give excessive rates of rainfall for durations of 2 hr and less, only.

(*f*) A single rain-gage gives a record of the precipitation at one point only, with no indication of the variation in any direction. It merely takes a sample, 1 ft wide, out of a storm that may have a width of 50 000 ft.

(*g*) A large number of storms might pass over a single gage before it would make a record of the maximum intensity of any one storm.

(*h*) It seems that no one has ever installed enough gages to show a reasonably correct picture of an excessive rain storm. In the Chicago District (see Fig. 1 and Table 1) with an area of about 250 sq miles, there are now (1937) fourteen rain-gages of the tipping-bucket type. The distance between them is still too great to give satisfactory storm patterns, although an effort has been made to use the available information.

These deficiencies probably explain inconsistencies in the results of rainfall studies and justify efforts to increase the statistical material applicable to a specific problem so as to reduce the percentage of probable errors. The addition of more gages multiplies the data each year and increases the points of application; for instance, in one Chicago Sewer District, comprising 4 500 acres, three gages were installed in 1933 to furnish data for a special study of the District as the entire run-off passes through a pumping station equipped with recording Venturi meters. It is hoped that some definite relation may be established between rainfall intensity, impervious area, rate of run-off, total run-off, and time.

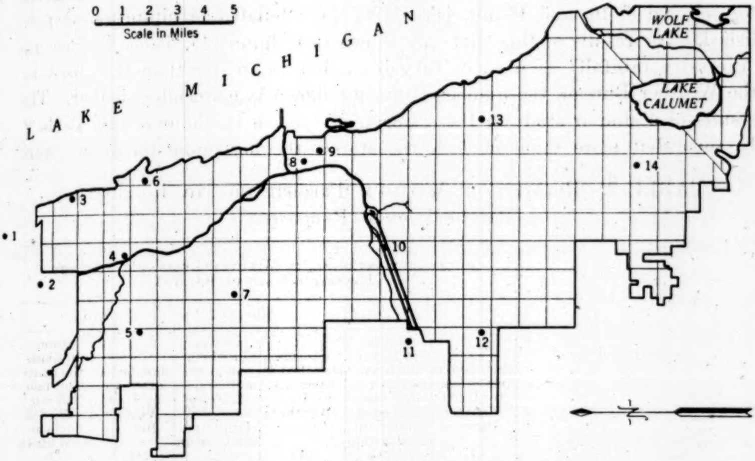

FIG. 1.—LOCATION OF RAIN-GAGES, CHICAGO, ILL. (SEE TABLE 1).

RELATION OF MAXIMUM PRECIPITATION TO TABULATED (PUBLISHED) QUANTITIES FOR 5, 10, AND 15 MINUTES

The tabulation of excessive rainfall published by the U. S. Weather Bureau shows the quantities for successive 5-min intervals, beginning with the excessive rate. The maximum may occur partly in one and partly in another of the 5-min intervals. When this occurs the published records do not show this maximum. An examination was made of all the original rain-gage charts of the excessive rainfall records for the Federal Building, in Chicago, for the 10-yr period, 1919–1928, to find the relation of maximum precipitation for selected 5, 10, and 15-min periods to the tabulated precipitation as published. The results of this study are shown in Column (1), Table 2. Because "excessive rainfall" as used in this discussion is greater than that used by the Weather Bureau, the number of storms shown is materially smaller. The results of a similar study of these storms are shown in Column (2), Table 2. In somewhat more than one-half the storms the maximum quantities were greater than those shown in the official tabulations for the given intervals. The increase averaged from 2 to 3% for that part of the record used for the curves.

TABLE 2.—RELATION OF MAXIMUM PRECIPITATION TO TABULATED PRECIPITATION AS PUBLISHED

Description	SUCCESSIVE INTERVAL, IN MINUTES, BEGINNING WITH THE EXCESSIVE RATE OF RAINFALL					
	5		10		15	
	Storms classified as excessive by U. S. Weather Bureau (1)	Storms in which the maximum rainfall rate exceeded minimum used herein (2)	Storms classified as excessive by U. S. Weather Bureau (1)	Storms in which the maximum rainfall rate exceeded minimum used herein (2)	Storms classified as excessive by U. S. Weather Bureau (1)	Storms in which the maximum rainfall rate exceeded minimum used herein (2)
Number of storms tabulated.....	65	12	62	17	52	18
Number of storms in which the maximum rate exceeded tabulated rates.................	42	6	33	11	29	11
Percentage excess of maximum rainfall over tabulated rainfall.	9.9	3.2	3.3	2.1	2.3	2.0

This record of one gage for ten years may be taken as an indication of the failure of the tabulated records to show maximum rainfall for short durations, but the data are too scanty to give general averages and no correction factor has been applied in this study.

NEW RULE OF THE UNITED STATES WEATHER BUREAU FOR TABULATION OF EXCESSIVE RAINFALL

The U. S. Weather Bureau adopted rules, in March, 1934, relating to the tabulation of excessive precipitation which are expressed by two formulas, one for the Southern States and one for the Northern States. Table 3, con-

TABLE 3.—LIMITS AT WHICH PRECIPITATION MAY BE CONSIDERED EXCESSIVE

Description	DURATION OF STORM, IN MINUTES										
	5	10	15	20	25	30	35	40	45	50	60
Depth of precipitation, in inches...........	0.25	0.30	0.35	0.40	0.45	0.50	0.55	0.60	0.65	0.70	0.80

tained in a set of instructions issued by the Weather Bureau, explains these rules It is based upon the formula:

$$d_a = t + 20 \dots\dots\dots\dots\dots\dots\dots\dots (1)$$

in which d_a is the accumulated depth, in hundredths of inches; and t is the time, in minutes. For stations in the Southern States (including North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Tennessee, Arkansas, Louisiana, Texas, and Oklahoma), where brief, heavy showers are comparatively frequent, the excessive rate, for the purpose of tabulation, is based upon the formula:

$$d_a = 2\,t + 30 \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

For a rain lasting 5 min, for example, the total depth in Table 3 would be 0.40 in.; for $t = 30$ min, $d_a = 0.90$ in.; and, for $t = 60$ min, $d_a = 1.50$ in.

The U. S. Weather Bureau rule provides that the accumulated depths are to be tabulated when the fall equals or exceeds the rates determined by Equations (1) and (2) and that all tabulations must show the accumulations for 60, 80, 100, and 120 min, even where the excessive rate does not continue for such periods.

The rule for the Northern District applies to Chicago. However, the storms rated as excessive in this paper are in accordance with the definition previously given. The data published under the new rules are more complete and permit of more accurate analysis inasmuch as the precipitation for excessive storms is given for intervals as long as 120 min, although the excessive rate may not have continued for that length of time. This was not done in records previous to 1933, and any precipitation occurring within the 120-min period, but subsequent to the expiration of the excessive rate, was not shown.

STATION-YEARS AND FREQUENCIES

The data on excessive rainfall from a single station are very scanty because the length of the record giving intensities for short durations extends over only a short term of years, and if storms of long-time frequencies occur in the record, it is difficult, if not impossible, to determine their frequencies. The best way to overcome this defect seems to be to combine the records of several stations and thus to obtain sufficient data to treat them statistically. The idea of combining records of different stations in hydraulic studies is not a new one. It was used by the late W. E. Fuller, M. Am. Soc. C. E.[3], by A. F. Meyer, M. Am. Soc. C. E.[4], and by the late Allen Hazen, M. Am. Soc. C. E.[5] The data in Meyer's compilation of excessive precipitation ended with the year 1914. Since then the total data available have been more than doubled by the publications of the U. S. Weather Bureau.

[3] *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

[4] "Hydrology", by A. F. Meyer, John Wiley & Sons, 1928.

[5] "Flood Flows", by Allen Hazen, John Wiley & Sons, 1930, p. 90.

If there are 10 stations with a 30-yr record for each station, there are 300 station-yr. A record that occurs three times in the entire 30 yr has a probable frequency of 100 yr for any one station, or the chance of such a storm occurring at a given station in any year is 1 in 100. In the same manner a record that occurs thirty times has an average frequency of 10 yr, and a record that occurs sixty times has a frequency of 5 yr. If the distribution were uniform and if each station showed that a certain record occurred six times in the 30 yr, the 5-yr frequency would be apparent, and the record of one station, in so far as this record was concerned, would be as good as the record of ten stations, but the distribution is not uniform and an average frequency is sought. The use of several rain-gages distributed throughout the area considered is a reasonable method of accumulating the needed data if the record extends over a considerable number of years.

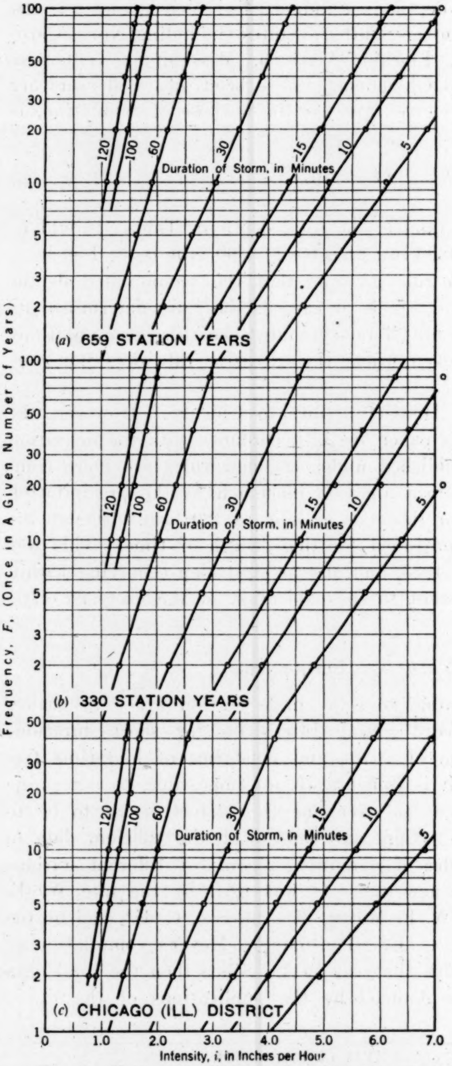

FIG. 2.—FREQUENCY-INTENSITY GRAPHS, FROM EQUATIONS OF THE FORM, $i = \frac{d_a}{t+b}$ (SEE TABLE 5).

INTENSITY CURVES ON SEMI-LOGARITHMIC PAPER

The curves from formulas for intensity of the compound interest law type when plotted on semi-logarithmic paper are straight lines, and, therefore, the intensities for any given duration have a constant difference for frequencies that vary in a geometric ratio, such as 5, 10, 20 and 40 yr.

The lines that depart most from the vertical show the greatest difference in intensities for any given frequencies; hence, in Fig. 2, the 5-min line shows the greatest differences and the 120-min line the least, as would be expected.

In 1930, C. S. Jarvis, M. Am. Soc. C. E., presented[6] a chart of frequency curves on semi-logarithmic paper, which shows the minimum and maximum annual precipitation for four stations, namely: Padua, Italy, 202 yr; Paris, France, 214 yr; Charleston, S. C., 137 yr; and, Boston, Mass., 111 yr. Commenting on "some interesting and useful relations" regarding periodic maximum and frequency curves, Mr. Jarvis calls attention to the fact that the mean monthly or the mean annual precipitation seems to form a simple arithmetical progression, whereas the related time intervals form a geometrical progression. His graph[6] illustrates, for the yearly precipitation, "how nearly the straight-line relation holds for frequency curves when they are thus plotted on semi-logarithmic paper." Similar results are apparent for monthly periods.

STATIONS STUDIED

The records of nineteen U. S. Weather Bureau Stations for all storms occurring in the years, 1915 to 1932 (several thousand in number), that were classified as excessive by the Weather Bureau, were examined for intensities and durations coming within the limits of this study. The records selected were summarized by classes and added to the Meyer summary for the earlier years. No correction factor was used for the precipitation corresponding to any duration.

The nineteen stations selected were: Albany, N. Y.; Asheville, N. C., Boston, Mass., Cairo, Ill., Chicago, Ill., Cincinnati, Ohio, Cleveland, Ohio, Detroit, Mich., Dodge City, Kans., Elkins, W. Va., Grand Haven, Mich., Indianapolis, Ind., Knoxville, Tenn., Madison, Wis., Memphis, Tenn., Moorhead, Minn., Pittsburgh, Pa., St. Paul, Minn., and Yankton, S. Dak. Independent studies and graphs were made for each of these nineteen stations for the 37 yr covered by the 1915–1932 data (18 yr) combined with the Meyer data (19 yr). A considerable degree of similarity was found with only such discrepancies as might be expected from data of such limited nature covering chance occurrences.

Graphs and formulas were derived from these data, covering the quantities, intensities, frequencies, and durations for excessive storms. It was found, by plotting the tabulated statistical results on semi-logarithmic paper for storms of 5, 10, 15, 30, 60, 100, and 120-min duration, that the data were best represented by straight lines, as shown in Fig. 3(*a*). The precipitation, in inches of rainfall, was plotted on the arithmetical scale and the number of storms exceeding the given depth of rainfall on the logarithmic scale. The means of class intervals were used in plotting the curves. For example, on the 30-min graph shown in Fig. 3(*a*), 353 storms were plotted against 1.05 in. of rainfall for the class interval extending from 1 in. to 1.10 in., it being assumed that as many storms in the class interval exceeded the mean as were below the mean. The class intervals vary for storms of different durations, but are the same for each duration in all these studies. With this

certain cases where the indicated frequency exceeded 100 yr, which is to be expected, as the correct frequency of rare storms is always a matter of uncertainty in a short record.

Some frequency lines are also shown on Fig. 3(*a*). The 10-yr frequency is represented by the horizontal line through the point, 65.9, which represents one storm in 10 station-yr. A frequency-quantity graph was derived directly from Fig. 3(*a*) by plotting the values of the depths for the 100-yr frequency line and the depths for the 5-yr frequency line, and drawing straight lines

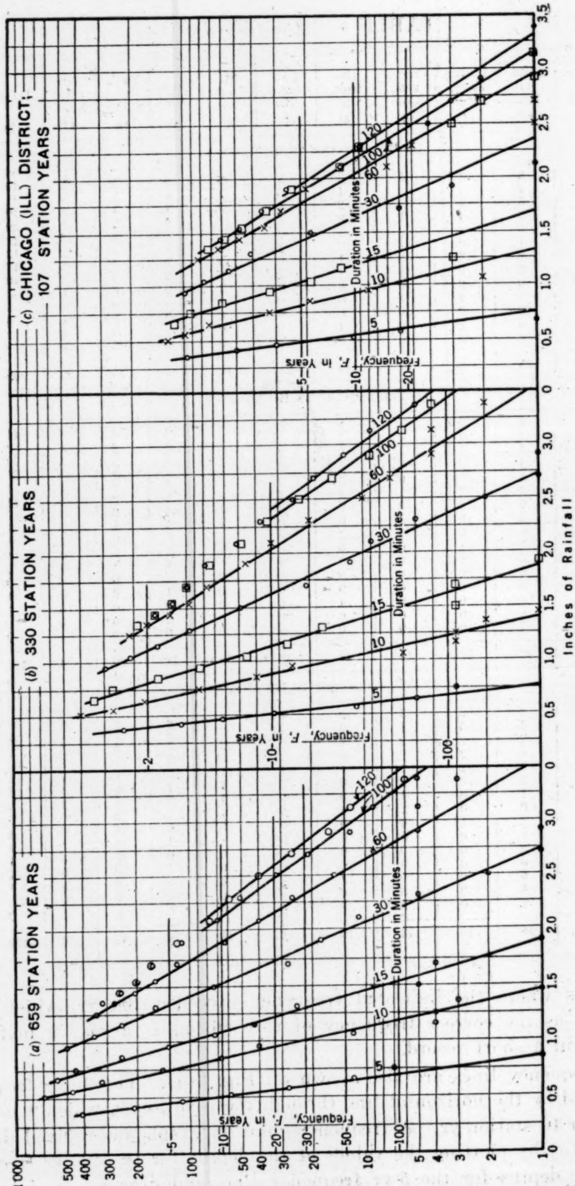

FIG. 3.—GRAPHS OF STATISTICAL DATA.

between the points plotted. In other words, such a graph would be similar to Fig. 3(*a*), except that the curves are inverted, and the logarithmic scale then gives the frequency for any number of years from 1 to 100.

Fig. 4 gives the relation between frequency and intensity for the nineteen stations. These graphs were obtained directly from the aforementioned frequency-quantity graph by converting the quantities for the various durations into intensities, or rates per hour, and by plotting the frequency on the logarithmic scale. This chart shows frequencies up to 100 yr, but as the data cover 659 station-yr, it might be reasonable to extend the graphs to an even higher limit.

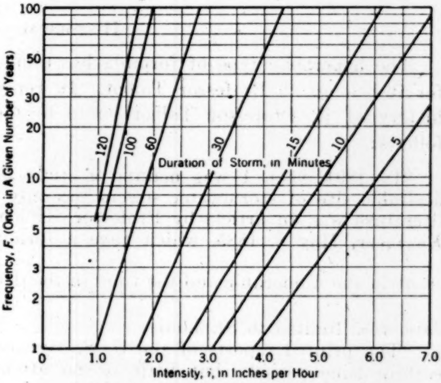

FIG. 4.—FREQUENCY-INTENSITY CURVES OF STATISTICAL DATA; 659 STATION-YEARS.

Although the relation between durations and depths of rainfall for any frequency appears to follow a law as expressed by logarithmic formulas, it was found that the hyperbolic type of formula represented by,

$$i = \frac{A}{t + b} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

was the best form for showing the relation between intensity and duration for storms not exceeding 120 min of a given frequency. (In Equation (3), A and b are abstract constants, as explained subsequently under the heading "The Constants in the Formulas for Intensity".) Formulas of this type were derived from the 659-station-yr data. These formulas were then plotted, as shown by dots in Fig. 2(*a*), and furnish a basis of comparison with the graphs as derived from the statistical data as shown on Fig. 4. The points as plotted from these formulas give a straight line for each duration, indicating a remarkable consistency in the formulas. These graphs give values very close to those shown by the statistical graphs, except in the case of the

TABLE 5.—VARIATIONS OF CONSTANTS IN THE FORM OF EQUATION (3)

5-min line, and probably the values given by the formula are more nearly correct for this duration than the values given by the statistics. The curves of Fig. 2(a) are variations of Equation (3), as defined by Item No. 1, Table 5.

HISTORICAL

The hyperbolic type of formula has been used since 1891, and the credit for it belongs to Professor Talbot. In reply to an inquiry concerning the history of it, Professor Talbot wrote to the writer on July 31, 1933, as follows:

> "In 1891 when I was making a study of rates of rainfall as affecting desirable size of stormwater sewers the only reference found in engineering literature was an article by Professor Nipher of St. Louis in the *American Engineer,* May 8, 1885, which gave a formula for intensity having a constant in the numerator and the time in the denominator $\left(i = \frac{360}{t}\right)$. Nipher's data were limited to St. Louis.
>
> "The printed reports of the U. S. Weather Bureau gave the rainfall for certain time periods, but little or no attention was given to the rate or intensity of the rainfall as such. After plotting the rates against time for all the data available in the published records of the U. S. Weather Bureau and for different sections of the Country and for the larger cities, my studies indicate that a formula of the form of a constant in the numerator and the time plus a constant in the denominator would best envelop the plotted points for 'rare rainfalls' and another of the same form those for what were called 'ordinary rainfalls.' The studies further brought out that the maximum rates shown by the accumulation of data were not greatly different for the several sections of the country considered (the maximum rates, not their frequency), a conclusion quite different from the views then commonly held.
>
> "The studies were published as 'Maximum Rates of Rainfall' in *The Technograph,* No. 6, 1891–92, University of Illinois. This article was republished in whole or in part in engineering journals and has been abstracted or referred to through the years in discussions and publications here and abroad. For thirty years hardly a year went by without seeing a reference to it in print.
>
> "So far as the form of the formula is concerned, it was devised by me, and I have seen nothing since that indicated a prior use by another. Mr. Kuichling told me later that he had used a straight-line formula in 1889. Mr. Rudolph Hering once showed me the rainfall plots he had made for New York City, but after reading my article he had not gone further in the study of the subject.
>
> "In the years intervening since the publication of 'Maximum Rates of Rainfall' there has been a great and valuable accumulation of rainfall statistics. It would not be strange if now a new constant or even a new form of formula would better fit the data. Naturally I am pleased to learn that the form of the formula devised by me so many years ago is useful in expressing the intensity of rainfall for Chicago."

Some of the hyperbolic formulas in common use are of the Talbot type. Formulas of this type that are used in other cities have been studied in connection with the frequency-intensity graphs, Figs. 2(a) and 4, and also on hyperbolic paper with varying results. Considerable variation in frequency has also been found for formulas of the exponential type such as,

$$i = \frac{A}{(t + b)^n} \quad \text{.........................(4)}$$

Thus far, it has not been found, in any of these investigations, that a formula of this type would give a constant frequency for all durations between 5 and 120 min. Rectangular hyperbolas fit the data better than any other curves and the Talbot type of formula is the simplest expression found for them for a given frequency.

LIMITATIONS OF FORMULA FOR INTENSITY

Although the hyperbolic type of formula appears to be singularly adapted to express the intensity for a given frequency, for excessive storms of durations not exceeding 120 min, it is, from its fundamental structure, not applicable for storms of long duration, as shown by the following analysis. The formula,

$$i = \frac{222}{t + 24} \quad \text{.........................(5)}$$

gives the intensity or rate per hour for a 40-yr frequency curve. If it is multiplied by $\frac{t}{60}$, the result will be the precipitation, d, for the time, t. Then:

$$d_a = \frac{222}{t + 24} \times \frac{t}{60} = \frac{3.7\,t}{t + 24} \text{.....................(6)}$$

The factor, $\frac{t}{t + 24}$, will always be less than unity for any value of t and, therefore, the value of d_a cannot exceed 3.7 in. for any time. When t becomes large, the change in d_a is small for successive changes in t, as shown by the following tabulation:

Duration, t, in minutes	Precipitation, d_a, in inches
120	3.08
600	3.56
1 440	3.64
2 880	3.67

As the rainfall in 10 hr, or 24 hr (600 min, or 1 440 min) may greatly exceed the corresponding values shown for d_a, Equation (6) is evidently not applicable for the longer durations.

A formula for depth of rainfall was derived as a function of log-time which fits closely the data used in the hyperbolic formula (Equation (3)) from $t = 10$ to $t = 120$ min and does not have the defect of reaching a maximum.

In the case of the 40-yr frequency, it was:

$$d_a = 1.89 \log t - 0.80 \text{.....................(7)}$$

The hyperbolic form is simpler for computation and is the one preferred when the time extends only to 120 min.

CURVES FOR TEN SELECTED STATIONS

After analyzing the data for the entire nineteen stations results were examined to discover the ten stations having characteristics similar to Chicago conditions. This was done for the purpose of securing data that corresponded most closely to the Chicago conditions, in order to amplify limited records available locally. The ten stations were: Cairo, Ill., Chicago, Ill., Cincinnati, Ohio, Detroit, Mich., Dodge City, Kans., Indianapolis, Ind., Knoxville, Tenn., Memphis, Tenn., St. Paul, Minn., and Yankton, S. Dak.

After selecting these stations an independent study of the records of the U. S. Weather Bureau for the 33 yr from 1900 to 1932, inclusive, was made and the excessive storms were tabulated as shown in Table 4. Similar tables, which are not shown, were prepared for the studies for 659 station-yr, and for Chicago. Graphs were made similar to the graphs prepared for the 659 station-yr in the preliminary studies.

It was found that the use of the data for storms of low intensity added little to the value or the accuracy of the graphs. In general, Table 4 includes only storms having intensities equal to or greater than those indicated in the definition of excessive storms. These intensities include all frequencies likely to be of interest to the designer of storm sewers for the reason that sewers should be designed to provide for storms of greater intensity than those likely to occur once a year or oftener.

Fig. 3(*b*) shows the statistical data for ten stations for the years, 1900 to 1932, inclusive, or a total of 330 station-yr plotted on semi-logarithmic paper, with the depth of rainfall shown on the arithmetical scale and the number of storms on the logarithmic scale Fig. 3(*b*) corresponds, for the ten stations, with Fig 3(*a*) showing the nineteen stations, and is similar in the relative position of the graphs. More than 1 800 excessive storms were tabulated and studied to make the chart for ten stations.

Fig. 2(*b*) shows frequency-intensity graphs for 330 station-yr plotted from the hyperbolic formulas which were derived from the statistical data. For the ten stations, Fig. 2(*b*) is comparable with Fig. 2(*a*) for the nineteen stations. With the exception of the 5-min and 10-min lines, the graphs fit the original data so nearly that they are practically coincident. From the formulas (Equation (3), and Items Nos. 1 and 2 in Table 5), the 5-min line is probably more nearly correct than the original data, as it gives larger values. The equation for the 60-min curve on this chart may be written in two forms:

$$i = 1.03 + 1.00 \log F \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

or,

$$F = 0.0933\ e^{2.3i} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which *e* is the Naperian base. The curves of Fig. 2(*b*) are variations of Equation (3), as defined by Item No. 2, Table 5.

Derivation of a Formula for the 60-Minute Graph on the Frequency Intensity Chart for 330 Station-Years (See Fig. 2(*b*))

Any curve that appears as a straight line on semi-logarithmic paper has an equation of the form:

$$y = k\ e^{rx} \quad \dots\dots (10)$$

in which k is a constant, and r is the rate of increase. Substituting F, the frequency, and i, the intensity, for y and x, Equation (10) becomes:

$$F = k\ e^{ri} \quad \dots\dots (11)$$

Taking values of i from the curve for the 60-min storm (Fig. 2(*b*)) when $F = 100$ and $F = 1$ and substituting them in Equation (11): $100 = k\ e^{3.03\ r}$; and, $1 = k\ e^{1.03\ r}$. Then, converting to the logarithmic form:

For $F = 100$:

$$\log 100 = \log k + 3.03\ r \log e \quad \dots\dots (12a)$$

for $F = 1$:

$$\log 1 = \log k + 1.03\ r \log e \quad \dots\dots (12b)$$

and, by subtraction,

$$2 = 2.00\ r \log e \quad \dots\dots (13)$$

Finally, $r = \dfrac{1}{0.4343} = 2.30$; and, by substituting this value in Equations (12) and solving simultaneously: $\log k = -1.03 = 8.97 - 10$; $k = 0.0933$; and, substituting in Equation (11):

$$F = 0.0933\ e^{2.3i} \quad \dots\dots (14)$$

Equation (14) may be reduced to the formula for intensity, as follows:

$$\log F = \log 0.0933 + 2.3\ i \log e \quad \dots\dots (15)$$

and since $2.3 \log e = 1$,

$$\log F = \log 0.0933 + i \quad \dots\dots (16)$$

and,

$$i = \log F - \log 0.0933 = \log F + 1.03 \quad \dots\dots (17)$$

which may also be obtained by inspection of Fig. 2(*b*). The equation for any other line on Fig. 2(*b*) can be obtained in a similar manner:

For $t = 120$,

$$i = 0.57 + 0.61 \log F \quad \dots\dots (18a)$$

for $t = 100$,

$$i = 0.67 + 0.70 \log F \quad \dots\dots (18b)$$

for $t = 60$,

$$i = 1.03 + 1.00 \log F \quad \dots\dots (18c)$$

for $t = 30$,

$$i = 1.80 + 1.46 \log F \qquad (18d)$$

for $t = 15$,

$$i = 2.73 + 1.87 \log F \qquad (18e)$$

for $t = 10$,

$$i = 3.32 + 2.03 \log F \qquad (18f)$$

and, for $t = 5$,

$$i = 4.18 + 2.25 \log F \qquad (18g)$$

The constant is the value of the intensity for the 1-yr frequency and the coefficient of log F is the 10-yr intensity minus the constant. As the logarithm of 10 is 1, it is apparent that the value of the 10-yr intensity is the sum of the constant and the coefficient.

THE CHICAGO CURVES

The methods of studying the nineteen stations and, later, the ten stations were then applied to the data of the U. S. Weather Bureau for the Chicago Station. Following the procedure previously described for the nineteen stations, a chart was prepared with graphs showing storms from 5 to 60-min duration, based on the statistical data for a period of 33 yr, which were all the official data available for that station, for excessive storms of those durations.

Other rain-gages in the Chicago District furnished records that might be combined with the data of the Weather Bureau Station, to give charts based on nearly three times the statistics of the single station. Thirteen rain-gages of the automatic type furnished the precipitation data for the City of Chicago used in this study. The location of the gages is shown in Fig. 1 and Table 1. Of these, two are maintained by the U. S. Weather Bureau (three in 1937), four by the City, and seven by the Sanitary District of Chicago (six in 1937). The distribution of the gages, although not ideal, is still fairly good as may be seen by reference to the outline map of Chicago in Fig. 1.

Three gages were established in 1933. Five gages have records beginning in 1926. The records of excessive precipitation from two of the automatic gages of the Federal Government extend back to 1919 and 1900. It is quite possible in combining these records that too much emphasis is given to records of recent years, but there is no obvious method for balancing this defect except by adding new data as they occur. Seven years of observation with the present number of gages will about double the data.

The official station (for observation purposes) of the U. S. Weather Bureau, in Chicago, was on the United States Court House (formerly the Federal Building) previous to 1926, when the official station was moved. Rosenwald Hall and the adjoining campus at the University of Chicago then became the official station (for observation purposes), although it had been in existence as an unofficial station of the Weather Bureau since 1916. The station on the U. S. Court House has been continued, but its records have not been published since 1925.

Curves Applying to the Chicago District

Fig. 3(*c*) shows the statistical data for the combined records of two Weather Bureau gages, and the several gages maintained by the City of Chicago and the Sanitary District of Chicago to the end of 1933, amounting to 107 station-yr. The longest record for one gage is for 34 yr. Fig. 2(*c*) shows frequency-intensity graphs for storms from 5 to 120-min duration, based on formulas derived from the foregoing statistics. The plotting of the formulas in this case shows the same consistency of the points on the lines and the relative position of the graphs that was shown in Figs. 2(*a*) and 2(*b*). The curves of Fig. 2(*c*) are variations of Equation (3), as defined by Item No. 3, Table 5.

Semi-Hyperbolic Paper

The Talbot formula, Equation (3), is a special form of the general equation $xy = k$, representing a rectangular hyperbola. Since the value of x varies as a hyperbola, the locus of the equation should be a straight line when plotted on semi-hyperbolic paper, that is paper graduated in one dimension on an arithmetical scale and in the other dimension on a hyperbolic scale.

As an investigation failed to disclose any hyperbolic paper of suitable size on the market, paper of this type was prepared. For the purpose a form of semi-hyperbolic paper of letter-sheet size was prepared with the hyperbolic scale covering 10 in. and the arithmetical scale, 7 in. The hyperbolic scale is derived from the formula for a rectangular hyperbola. In this case the base line equals 10 in., and the divisions from the right-hand margin are equal to ten times the reciprocals of the numbers from 1 to 10. For example: The line, 5, is ten times $\frac{1}{5} = 2$ in. from the margin; the line, 2, is ten times $\frac{1}{2} = 5$ in. from the margin; the value of the line at the left margin is 1.0; and the value of the line at the right margin is infinity.

Equations of the form, $xy = k$, which includes equations for intensity of rainfall, such as $i = \dfrac{126}{t + 18}$, appear as straight lines on this paper. It has a range for $i = 1$ to $i = 10$; and a range for $t = 0$ to $t = 120$.

Intensity Curves on Semi-Hyperbolic Paper

Fig. 5 shows, on semi-hyperbolic paper, the intensity-duration relationship for storms varying in frequency from 2 to 80 yr as determined by the formulas derived from the studies for the ten stations previously mentioned, including 330 station-yr (see Table 5). The frequencies shown, for $F = 5, 10, 20, 40,$ and 80 yr, are in a geometrical progression; the 2-yr frequency is an exception. The graph for the 10-yr frequency is midway between the graphs for the 5-yr and 20-yr frequencies, and the graph for any term in the geometrical progression lies midway between the graphs of the adjacent terms. The application of this relationship for interpolating intermediate frequencies and for deriving formulas will be discussed subsequently.

The intensity curves on hyperbolic paper are best adapted for use in preparing sewer designs. The range of the charts is sufficient to include all except the larger sewer projects. Curves are given for five or six different frequencies and for durations of as much as $t = 120$ min with 2-min intervals. Graphs for other frequencies than those shown, can easily be added if needed.

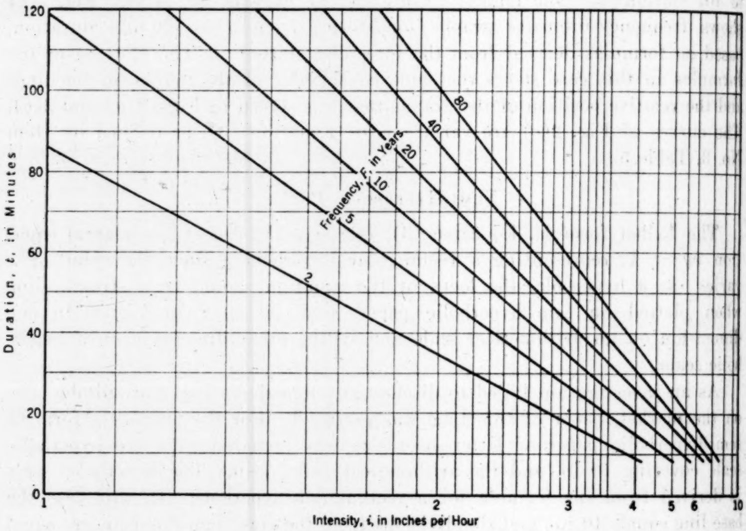

FIG. 5.—INTENSITY-DURATION GRAPHS; 330 STATION-YEARS (SEE TABLE 5, ITEM NO. 2).

A brief examination of these charts reveals the great importance of the time element. A change of 10 min in the estimate of the concentration period, as from 50 to 40 min, may be the equivalent of changing from a 5-yr frequency to a 10-yr frequency; for example, the intensity for a 5-yr frequency is 2 in. for 50 min, and 2.33 in. for 40 min, the latter being the same as the intensity for a 10-yr frequency for 50 min.

THE CONSTANTS IN THE FORMULAS FOR INTENSITY

The constants in the formulas for intensity were found originally by trial to make the formulas fit the values in the statistical data. This is easily done with the slide-rule. They may also be found by solving Equation (3), using the values for i and t that are obtained from the graphs of the statistical data (Fig 3). After the formulas were determined for the various frequencies, the results were verified, and the accuracy and consistency of the formulas and data were examined by plotting the constants in the numerators and denominators on semi-logarithmic paper.

Fig. 6 shows the constants used in the intensity formulas applying to the data for nineteen Weather Bureau stations. The values for the constants in the numerators lie on a straight line with one exception and the values used in the denominators are close to a line with very slight curvature. All the constants in these formulas are whole numbers, as it seemed that the introduction of fractions would be a needless refinement. By the use of the graphs the approximate values of the constants in the formulas for any desired frequency from 2 to 100 yr may be obtained, and formulas for the intensity for any desired frequencies within the range of the chart may be written. This gives a simple method for computing two values and drawing any intermediate frequency line on the hyperbolic chart.

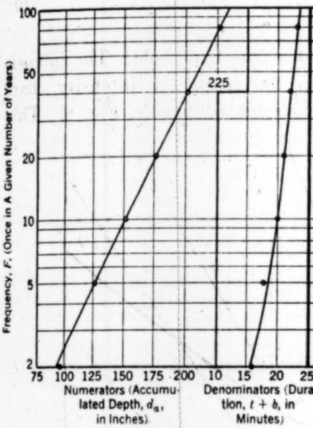

FIG. 6.—CONSTANTS IN INTENSITY FORMULAS, 659 STATION-YEARS.

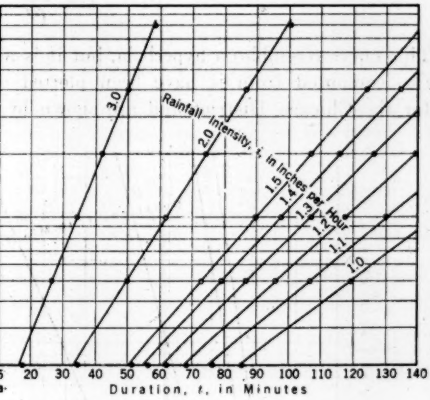

FIG. 7.—FREQUENCY DURATION GRAPHS FOR THE INTERPOLATION OF FREQUENCIES.

GRAPHICAL INTERPOLATION OF FREQUENCY LINES

A graphic method for interpolating frequencies on a hyperbolic chart of rainfall intensities for the ten stations, is shown in Fig. 7, in which intensity lines are drawn with frequency and time as the co-ordinates. In other words, it is a frequency-duration chart for various intensities. The points were found by solving for time in the intensity formulas for the several frequencies with assumed intensities from 1 in. per hr to 3 in. per hr. These points, for frequencies of 5 yr, or more, when plotted on the semi-logarithmic paper give a straight line for each intensity; for example, if it is desired to interpolate on the hyperbolic chart, Fig. 5, a line giving the intensities for a frequency of 15 yr, two values should be found for the time for that frequency, using different intensities. For an intensity, $i = 3$, Fig. 7 gives the time, $t = 39$ min, and for $i = 1.4$, $t = 108$ min. This permits the plotting of two points on the 15-yr line on the hyperbolic chart (Fig. 5) and the drawing of a straight line through these points, which will give the intensities for any time up to 120 min.

The formula adopted in 1914–15 for use in Chicago was of the form of Equation (4):

$$i = \frac{28}{t^{0.7}} \qquad (19)$$

This curve resembles a hyperbola, but it is not a true hyperbola. The intensities computed from it have been plotted on the frequency intensity chart for the Chicago District and are shown by the curved line in Fig. 8. This graph indicates that the frequencies represented by Equation (19) vary from about 3 yr to more than 20 yr. Before these studies were made it was thought that the frequency corresponding to the intensities obtained by Equation (19) was approximately 5 yr, but such is the fact only for durations of 15 and 120 min, and it is not true for storms of other durations.

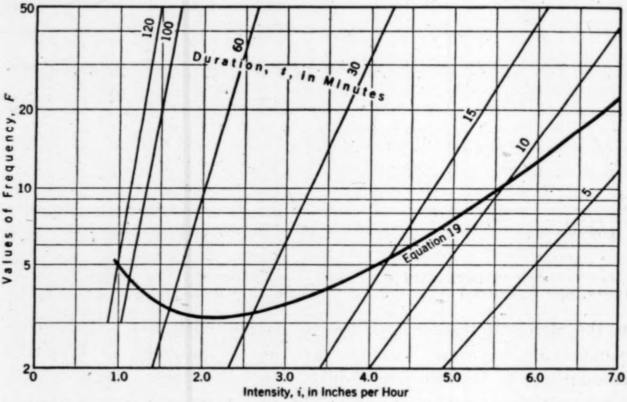

FIG. 8.—CURVES SHOWING VARIABLE FREQUENCY OF OLD FORMULA.

CONSTANT RATIO FOR FREQUENCIES WHEN INTENSITIES INCREASE BY A FIXED SUM

A characteristic of any formula which plots as a straight line on semilogarithmic paper, is that adding a fixed sum to the intensity will multiply the frequency by a fixed sum. In other words, successive additions of a fixed sum to the intensity will correspond to frequencies with a constant ratio. As an example, consider the following quantities picked from the 60-min frequency curve for 330 station-yr:

Intensity, in inches	Frequency, in years	Intensity, in inches	Frequency, in years
1.25	1.6	2.00	8.9
1.50	2.85	2.25	16.0
1.75	5.0	2.50	28.5

In each case, the ratio between successive frequencies is consistently 1.78.

RATIO OF DEPTHS OF RAINFALL (AND INTENSITIES) FROM CURVES FOR 330 STATION-YEARS

Table 6 shows depths of rainfall for storms of 1, 10, and 100-yr frequency for durations of 5, 10, 15, 30, and 60 min, taken from graphs; it also shows the computed ratio of the depth corresponding to a frequency higher than the ratio for the next lower frequency. The precipitations for various durations are shown, but the intensities will have the same ratios.

TABLE 6.—COMPARISON OF FREQUENCY STUDIES

Frequency, F, in years (1)	Duration, t									
	5		10		15		30		60	
	d_a, in inches (2)	Ratio (3)	d_a, in inches (4)	Ratio (5)	d_a, in inches (6)	Ratio (7)	d_a, in inches (8)	Ratio (9)	d_a, in inches (10)	Ratio (11)
1	0.34		0.54		0.67		0.91		1.04	
		1.50		1.63		1.70		1.79		1.96
10	0.51		0.88		1.14		1.63		2.04	
		1.33		1.40		1.42		1.44		1.49
100	0.68		1.23		1.62		2.35		3.04	

An equation such as,

$$i = \frac{C F^n}{(t + 7)^{0.7}} \quad \dots\dots (20)$$

will not fit the data in Table 6 because F, with a constant exponent, indicates a constant ratio of the intensities for all durations when the frequencies are in a geometrical progression. The ratio of intensities actually increases with the duration and decreases with the frequency in Table 6.

INTERPOLATION OF FREQUENCY CURVES BY GEOMETRIC MEAN

Charts on hyperbolic paper show that if the frequency lines are in a geometrical progression they will intercept a given intensity line with equal intervals (time) between them; for example, the 10-yr frequency line in Fig. 5 crosses the 2-in. intensity line half way between the 5-yr and the 20-yr frequency lines. Similarly, the line midway between the 5-yr and 10-yr lines will have a frequency of 7.07 yr, which is the square root of 5 × 10, and the line midway between the 10 and 20-yr lines will have a frequency of 14.14 yr, which is the square root of 10 × 20. A geometrical progression has the form,

$$x = a + ar + ar^2 + ar^3 + ar^4 \dots + ar^{n-1} \quad \dots\dots (21)$$

in which a = the first term; r = the ratio; and n = the number of terms. The ratio of the last term to the first term $\left(\frac{\text{Last term}}{\text{First term}}\right)$ is:

$$\frac{a\,r^{n-1}}{a} = r^{n-1} \quad \dots\dots (22)$$

Then, for the interpolation between $F = 5$ and 10, or $F = 10$ and 20:

$$\log r = \frac{1}{n-1} \log 2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

When the first and last terms are given, all the intermediate terms may be found.

Solving a 5-term series for three intermediate frequencies between 5 and 10 yr gives lines for $F = 5.95$, 7.07, and 8.41 yr, equally spaced. These values may be found by taking square roots, but when the exact position is required for an integral frequency, it is generally necessary to find an exponent by logarithms.

The integral numbers, 5, 6, 7, 8, 9, and 10, apparently, are terms in an arithmetical progression, but they are also approximate terms in a geometric progression that has a large number of terms (say, 1 001). Applying this method it is found that the spacing for the frequencies, $F = 6$, 7, 8, and 9 will be, respectively, 26.3%, 48.5%, 67.8%, and 84.8% of the distance between the 5-yr and the 10-yr frequencies. Intermediate integral frequencies between 10 and 20 will have the same proportionate spacing.

Difference in Time When Frequencies Are in Geometrical Progression

If the several formulas for intensity used in Fig. 5 (see Table 5, Item No. 2) that were derived from the chart showing the data for 330 station-yr are solved for the time with the same assumed intensity, it is found that the differences in time or in duration are constants for each intensity when the frequencies are in a geometrical progression. This is also true within narrow limits for the corresponding formulas for intensity for the Chicago District. This characteristic indicates a possible method for drawing additional curves on a chart.

TABLE 7.—Differences in Duration Time, Δt

Frequency, F	Intensity of Rainfall, in Inches per Hour							
	1		2		3		4	
	Time, t, in minutes	Difference, Δt	Time, t, in minutes	Difference, Δt	Time, t, in minutes	Difference, Δt	Time, t, in minutes	Difference, Δt
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
5	108		45		24		13¾	
		24		11		6⅔		4¼
10	132		56		30⅔		18	
		24		11½		7⅓		5¼
20	156		67½		38		23¼	
		24		11½		7⅓		5¼
40	180		79		45		28½	
		24		11½		7⅓		5¼
80	204		90½		52⅓		33¾	

Table 7 gives values of Δt from the formulas for 659 station-yr for frequencies of 5, 10, 20, 40, and 80 yr (see Table 5, Item No. 1). From inspection of Table 7 it appears that,

$$\Delta t = \frac{25 - i}{i} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

when frequencies form a geometrical progression. If $i = 2$ in. per hr, $\Delta t = \frac{25-2}{2} = \frac{23}{2} = 11\frac{1}{2}$; and, if $i = 4$ in. per hr, $\Delta t = \frac{25-4}{4} = \frac{21}{4} = 5\frac{1}{4}$. The differences are constant for a given intensity when the frequencies vary as in a geometrical progression.

CONCLUSIONS

The following conclusions are indicated by the foregoing arguments:

(1) The statistical method which combines station-years affords a means for studying rainfall data which gives reasonably regular and consistent results.

(2) Semi-logarithmic and hyperbolic papers are effective tools in studies of rainfall.

(3) For the shorter durations, the inlet time is an important factor in the time of concentration, as suggested in the comment on Fig. 5. Studies to find its probable mean value are desirable.

(4) Formulas such as Equation (7) indicate that when the durations are in a geometrical series the differences in rainfall values are a constant. This suggests a method that may be useful in a study of storms exceeding 120 min. Fig. 5 indicates that when the frequencies are in a geometrical series the differences in durations for a given intensity are constant. These relations would seem to be more than a coincidence and may be worthy of more extended examination.

(5) For the 5-yr and the 10-yr frequencies a close degree of similarity is shown for intensity values by the curves for the Chicago District and those for the 330 station-yr, except for 5-min and 10-min durations.

(6) The frequency-intensity curves give the probable intensity of rainfall for certain durations for a single gage. The average intensity over a large area, of course, is less than the maximum intensity. The ratio of this average to the maximum intensity is as yet unknown, and is one of the factors needing further investigation. One of the methods suggested for overcoming this difficulty in sewer design is the use of a frequency which varies in some inverse ratio with the duration or time of concentration. The frequencies that should be used in sewer design, although theoretically a matter of economics, are actually a matter of judgment based on experience.

(7) A study should be made of the relation of average intensities to maximum intensities of rainfall on small areas, such as may be used in sewer design, say, to 10 000 acres. This would require a considerable number of gages spaced in a regular pattern so as to permit the drawing of isohyetals and the computation of average depths of rainfall. It is believed that the frequency graphs give values for areas that are comparable with the size of sewer districts, and that the maximum size of such areas may be between 1 000 and 10 000 acres.

(8) The values obtained from the charts developed for the Chicago District have greater statistical foundation and appear to be more reliable than

any curves previously used by the Board of Local Improvements, City of Chicago. These charts are now (1937) being used by the engineers of the Board.

ACKNOWLEDGMENTS

Co-operation and assistance in the work outlined in this paper have been given in various ways by the following: The Sanitary District of Chicago, through the members of its Engineering Staff (Philip Harrington, Chief Engineer, O. L. Eltinge, M. Am. Soc. C. E., Engineer of Sewer Design, and L. W. Hall, M. Am. Soc. C. E., Hydraulic Engineer); the U. S. Weather Bureau, by W. R. Gregg, Chief of Bureau, Washington, D. C., and C. A. Donnel, Principal Meteorologist in Charge, Chicago, Ill.; Loyola University, Chicago, by its President the Rev. R. M. Kelly, S. J.; the City Engineer of Chicago, the late Myron B. Reynolds, and the Water Purification Division of the City Engineering Department; the late George C. D. Lenth, M. Am. Soc. C. E., Consulting Engineer, Chicago; T. S. Ford, Assistant Chief Engineer, Board of Local Improvements, and A. L. Appelbaum, Junior Engineer; and A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., as previously noted.

DISCUSSION

VICTOR H. COCHRANE,[7] M. AM. SOC. C. E. (by letter).—The remarkably consistent results obtained by the authors and other investigators indicate that the hyperbolic, or Talbot, type of formula is correct for precipitation lasting two hours or less. For some years the writer has made use of a formula giving the intensities of precipitation for various periods in terms of I, the precipitation in 1 hr. If in a given case, I is known or assumed, the proper intensities for other periods from 5 to 120 min may be calculated from the formula,

$$i = \frac{60 + n\,I}{\dfrac{t}{I} + n} = \frac{(60 + n\,I)\,I}{t + n\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots(25)$$

in which n is a constant depending upon the frequency, F. Its value varies from approximately 8 for $F = 100$ to about 12 for $F = 1$. It may be assumed according to the formula,

$$n = 12 - 2 \log F \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(26)$$

Combining Equations (25) and 26):

$$i = \frac{60 + (12 - 2 \log F)\,I}{\dfrac{t}{I} + (12 - 2 \log F)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(27)$$

If $F = 10$, $n = 10$, an average value. In case it is desired to use a value of I for which the frequency is unknown, this average value of n may be used for practical purposes.

TABLE 8.—COMPARATIVE VALUES OF i.

Elapsed time, t, in minutes	FREQUENCY EQUALS ONCE IN EVERY:					
	2 yr.		10 yr.		100 yr.

.....	.....	.....	.....	.....	.....	.....
.....	.....	.....	.....	.....	.....	.....

Table 8 shows comparative results computed from Equations (18) and (27). The fact that hyperbolic curves fit rainfall data covering short periods suggests that a formula giving flood flows from small water-sheds should likewise be hyperbolic.

LeRoy K. Sherman,[8] M. Am. Soc. C. E. (by letter).—Rainfall data are essential for the design of storm sewers and many other works. Analysis and interpretation of the data are of equal importance. The utilization of station-years in statistical methods, where such stations are near isohyetals for the same rainfall durations and frequencies, appears to be sound. Stations with materially different precipitation characteristics, such as Chicago, Ill., and Nashville, Tenn., should not be grouped together. Stations, such as St. Paul, Minn., Chicago, and Central New York State, all near the same isohyetal, may properly be placed in the same group.

The authors give preference to the hyperbola type of curve to express the rainfall relations. Others who have made similar studies prefer the exponential type of rainfall equation. In so far as the mathematical expression closely fits the data, the form of expression is relatively unimportant. The form which fits the widest range of observations is frequently the most desirable.

An examination of a large number of automatic rain-gage records in the District of Columbia[9] showed few instances of even approximate uniform rainfall rates for periods of 30 min or more. A fair average rainfall pattern was triangular in form, with time duration as the base and the peak rate at twice the average rate. These rain irregularities are partly "ironed out" on large areas during the time of run-off. Does the same apply to small urban areas? The authors' diagrams show that 2 in. of rain may fall during 1 hr: 1.3 in. in 20 min, and 0.7 in 40 min.

The rational method is now commonly used to estimate run-off from severed areas. The average hourly rate of rain for the period of concentration is used. It is pertinent to find what, if any, difference in run-off exists under the assumption of the average and the actual rates of rain.

The writer has determined this for a particular case—a severed area of 420 acres in Evanston, Ill., north of Chicago. The run-off characteristics of this area are given in a paper by S. A. Greeley,[10] M. Am. Soc. C. E. The writer has derived the typical percentage distribution of run-off from this area so as to conform to Mr. Greeley's time-run-off data. He has applied his own unit hydrograph method[11] and the same method as improved by Merrill M. Bernard,[12] M. Am. Soc. C. E., and by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt,[13] Assoc. M. Am. Soc. C. E.

A 10-yr storm for 50 min was taken. By Fig. 5, the average intensity of rain per hour for 50 min is 2.34 in., or a total of 1.95 in. The initial and infiltration loss was taken at 0.45 in. Under these conditions, the peak rate of run-off, by the rational method, is 755 cu ft per sec. The peak run-off for this same case, computed by the unit hydrograph method, is practically the same (762 cu ft per sec) as shown in Table 9(*a*). If the rain is continued beyond the time of concentration, the run-off rate (762 cu ft per sec, in Column (8), Table 9), will remain constant.

The peak run-off for this non-uniform rate of rainfall is 890 cu ft per sec (Table 9(*b*)). This is about 17% greater than the run-off due to uniform rainfall. One may conclude that, for a given coefficient or a rate of loss, the rational method will forecast the minimum rate of run-off corresponding to the storm duration and frequency. On large natural areas, with flood-producing storms lasting for several days, and where two-thirds of the total rainfall commonly occurs in one day, the use of average storm rates is inadmissible.

All of the foregoing goes to show the importance of rainfall data segregated into divisions of duration-intensity-frequency, such as the authors have presented.

J. O. JONES,[14] ASSOC. M. AM. SOC. C. E. (by letter).—A method of increasing the size of the sample of excessive precipitation data for storms of short duration (not exceeding 120 min) is described in this paper. The writer agrees that there is no single station record long enough to give what may be regarded as a fair sample of the total "population" of such data. In any statistical study of chance events the methods of statistics assume that an unbiased sample is available. The authors are to be congratulated for a fine contribution to a difficult and important subject.

It may be a debatable question whether it is permissible to combine the records of stations widely separated geographically, unless the rainfall characteristics are similar in other respects. As an extreme example, one would scarcely feel justified in combining the record of a station in Assam, (where the warm southwest monsoons from the Indian Ocean coming in contact with the Himalayas produce precipitation of from 400 in. to 800 in. per yr) with that of Boise, Idaho.

TABLE 10.—RAINFALL CHARACTERISTICS, STATE OF KANSAS

Division	Average coefficient of variation	Average ratio of the minimum to the mean	Average ratio of the maximum to the mean
Eastern	0.21	0.60	1.50
Middle	0.25	0.55	1.63
Western	0.28	0.49	1.72

It does seem reasonable to combine the records from a small area, such as the Sanitary District of Chicago, or even an entire State, where the rainfall characteristics are similar over the State. This the writer has done for the State of Kansas. There is some difference in the rainfall characteristics of Eastern Kansas when compared with the western part of the State. The average annual rainfall varies from about 17½ in. in Longitude 101° to 40 in. in the southeast corner of the State; but the time of occurrence is similar, being greatest in the warm months. As regards annual rainfall, the coefficient of variation and the coefficient of skew are not greatly different for the eastern as compared to the western part of the State. For eighteen stations in the Eastern Division, thirteen in the Middle Division, and eleven in the Western Division, the average coefficient of variation, the average ratio of the minimum to the mean, and the average ratio of the maximum to the mean is as shown in Table 10. Thus, it appears that the annual rainfall is less and more variable in the western part of Kansas. The differences in the statistical parameters, however, are not great. The monthly distribution is similar over the State, although the total depth, month by month, is greatest near the eastern border.

In view of the foregoing, it seems permissible to combine the records of excessive precipitation for the five U. S. Weather Bureau stations within the State, together with Kansas City, Mo., which is on the eastern border. The lengths of the records included in the study are: Concordia, 1908 to

---

1929; Dodge City, 1892 to 1929; Iola, 1906 to 1929; Kansas City, 1899 to 1929; Topeka, 1899 to 1929; and Wichita, 1903 to 1929—a total of 167 station-yr. These data include all storms for which the depth of precipitation is equal to or exceeds the quantities given by the authors in Table 3. From the records the frequencies in Table 11 were compiled. The values given in the left-hand column, "Inches of Rainfall," are the central values of groups; for example, for rainfall of 5-min duration, the depth, 0.275 in. includes all values from 0.25 in. to 0.29 in., 0.275 in. being the central value of the group.

From the data in Table 11 the usual statistical parameters were calculated for each station separately, with the result shown in Table 12. The remarkable agreement among the several stations, for the several durations, as regards the mean and the coefficient of variation, indicates that the data for the several stations are comparable. The somewhat greater variation in the coefficient of skew is not particularly significant considering its relatively large probable error when the coefficient is large and the sample is small.

TABLE 12.—EXCESSIVE PRECIPITATION IN KANSAS, U. S. WEATHER BUREAU STATIONS

The coefficient of skew for the Kansas City data is greater than the average of all the stations for all durations except those of 5 min and 100 min. This is the effect of a single storm, August 23, 1906, which was an unusual one.

When the records of the stations are combined the result given in Table 13 is obtained. A typical histogram and frequency curve is shown for the 5-min duration in Fig. 9. The frequency curve is fitted to the data by Pearson's Type III curve.[15]

TABLE 13.—EXCESSIVE PRECIPITATION; SUMMARY OF STATISTICAL PARAMETERS, KANSAS DATA

Total frequency, F (1)	Duration, in minutes, t (2)	Average intensity, in inches per hour, i (3)	Coefficient of variation, c_v (4)	Coefficient of skew, c_s (5)
1 243	5	3.05	0.382	1.53
1 228	10	2.56	0.366	1.69
1 136	15	2.21	0.385	1.50

299	45	1.66	0.392	1.68
184	60	1.50	0.407	1.67
97	80	1.40	0.402	1.58
46	100	1.38	0.410	1.43
21	120	1.24	0.338	0.24
Average*	...	....	0.386	1.55

* The average does not include the 120-min. duration, because of the small total frequency.

Using the average intensities, i (Column (3), Table 13), and the average values, $c_v = 0.386$ and $c_s = 1.55$, the ogive curves, Fig. 10, were constructed by the use of Foster's skew factors.[16] The "raw" data for the 5-min duration

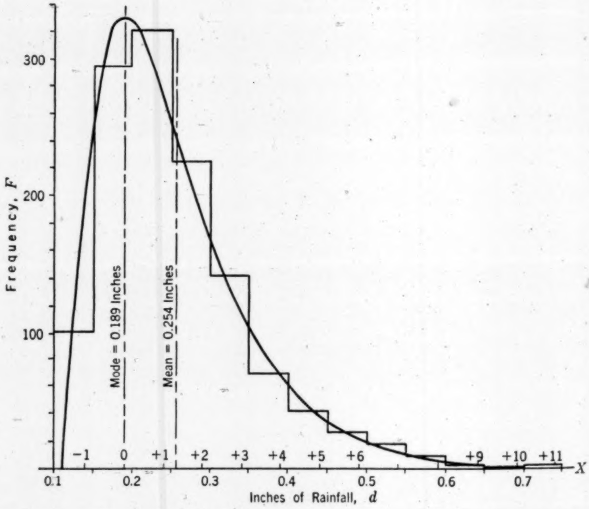

FIG. 9.—EXCESSIVE PRECIPITATION IN KANSAS; INCHES OF RAINFALL IN 5 MINUTES; U. S. WEATHER BUREAU STATIONS.

---

[16] *Loc. cit.*, p. 162.

is compared with the ogive curve obtained by the use of Foster's skew factors, and with the curve obtained by the use of Pearson's Type III frequency curve, in Fig. 11. No comparison was made with the "raw" data for the other durations. The labor of computing the ogive curve by means of Pearson's equation is prodigious. An examination of the method used by Foster[17], in deriving his skew factors for the Type III curve, leaves one with the conviction that the ogive curve, obtained by the application of the skew factors, will agree closely with that obtained from Pearson's equation, as it does for the 5-min duration.

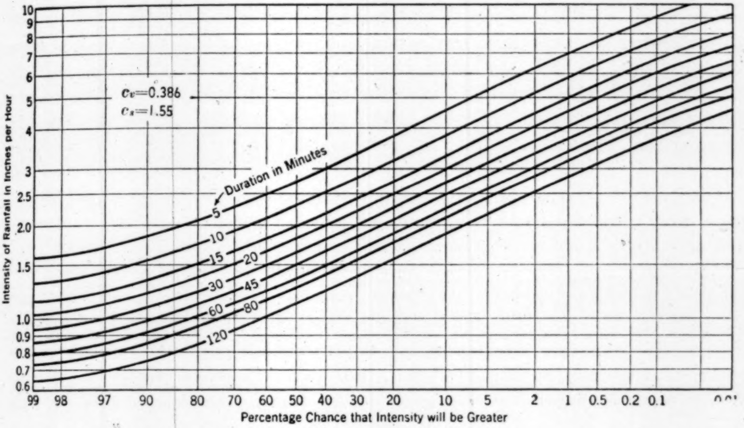

FIG. 10.—EXCESSIVE PRECIPITATION IN KANSAS; U. S. WEATHER BUREAU STATIONS.

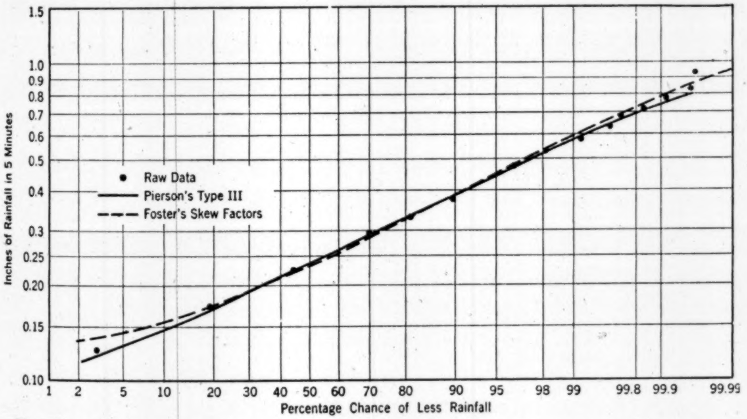

FIG. 11.—COMPARISON OF RAW DATA WITH FOSTER'S SKEW FACTORS AND PEARSON'S TYPE III FREQUENCY CURVE.

---

[17] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 159 *et seq.*

Equations 18(*a*) to 18(*g*) yield results which agree closely with Meyer's[18] equation for his Group 3; but a comparison with the results from the ogive curves is difficult. It depends upon what is meant by the term, "frequency". To state that a rainfall has a frequency of "once in 100 yr" does not necessarily mean that it has a 1% chance of occurring. There is some danger in assuming that because a certain maximum intensity has only been recorded once in 100 station-yr it, therefore, has a frequency of once in 100 yr. At Topeka, for the 5-min duration, an intensity of 6.9 per hr was experienced only once prior to 1929. In the interval, 1929 to 1935, inclusive, an intensity of 6.9 in. per hr was experienced once, and an intensity of 8.0 in. per hr was experienced once. Thus, prior to 1929 an intensity of 6.9 in. per hr had a frequency of once in 30 yr, but by the end of 1935 that intensity had a frequency of once in about 12 yr. Of course, by taking a large number of station-years such absurdities are "ironed out".

It would seem to be more logical to apply the methods of statistical analysis to chance events, and some statement involving the term, "percentage chance", would be preferable to the term, "frequency", as commonly used. To illustrate, there are on the average about four excessives per year, of 15-min duration, at Dodge City, whereas, at Topeka, there are on the average about eight. For any one of these excessives there is a 50% chance that it will exceed 2.0 in. per hr; a 10% chance that it will exceed 3.3 in. per hr; a 1% chance of 5.1 in. per hr; and 1 chance in 1 000 of an intensity of 6.7.

The Talbot formula has long been a favorite, because of its simplicity and its successful use in design. Considering the paucity of data at the time it was first proposed, it has given remarkable results in the design of storm sewers. It is not a good 'fit", however, to the record of a single storm. It can be stated in the form,

$$i\,t = A - i\,B \qquad \text{..................} (28)$$

in which $i\,t$ (intensity times duration) is the y-variable and i (intensity) is the x-variable. In this form, it is the equation of a straight line, A being the intercept on the y-axis and B, the slope of the line. In Fig. 12 is shown the intensity duration of the four greatest storms that have been recorded at Kansas City. Only one of these storms, that of September 6 and 7, 1914, is a good approximation to a straight line. The storms of June 8, 1910, and September 15, 1914, approximate a straight line if the 5-min and 10-min durations are omitted.

The result is little, if any, better when the combined data of several stations are considered. In Table 14 is listed the twenty greatest intensities from the record of 167 station-yr for the State of Kansas, arranged in order of magnitude without regard to the location of the station. These data, when plotted as in Fig. 12, are irregularly curved lines until the high orders of magnitude are reached.

---

[18] "Hydrology," by Adolph Meyer, M. Am. Soc. C. E.

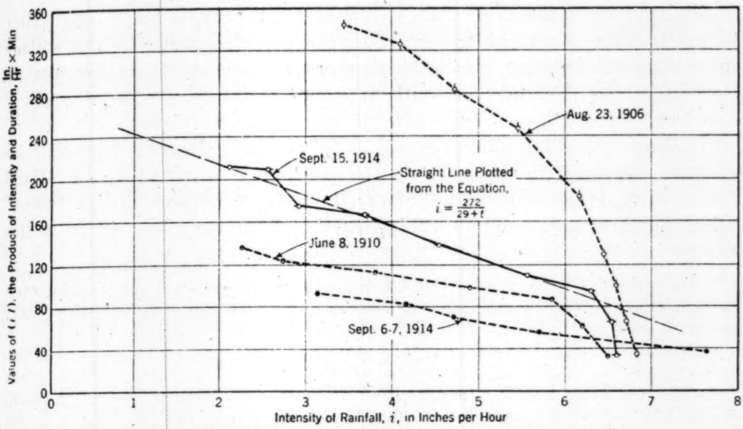

FIG. 12.—EXCESSIVE PRECIPITATION, KANSAS CITY, MO.

The writer is forced to the conclusion that attempts to generalize, in the form of an algebraic equation, are futile as far as conditions in Kansas are concerned. Formulas are convenient, and, in the hands of an expert, may serve a useful purpose, but they appear to be so easy to apply that they are likely to lead to absurd results in the hands of the inexperienced. It would seem that the histogram or the ogive curve is preferable.

TABLE 14.—MAXIMUM INTENSITIES OF RAINFALL IN KANSAS, ARRANGED IN THE ORDER OF MAGNITUDE

	DURATION IN MINUTES									
	5	10	15	20	30	45	60	80	100	120

CHARLES W. SHERMAN,[19] M. AM. SOC. C. E. (by letter).—The writer is particularly impressed by the almost unqualified faith of the authors in the assumption that the total number of station-year records may be used in studies of frequencies without regard to the matter of geographical locations, topographical conditions, or meteorological cycles.

Perhaps the first extensive use of combined records from various stations appeared in Part V of the Technical Reports of the Miami Conservancy District, entitled "Storm Rainfall of Eastern United States," which appeared originally in 1917. Quoting from the 1936 edition of this report:

> "In order to utilize all existing records that possessed any value, even though they differed materially in length, a method was adopted which may be explained as follows:
>
> "Assume a number of rainfall stations, say, five, located within an area possessing uniform rainfall characteristics. At station A complete records have been kept for a period of 70 years; at station B, for 40 years; at station C, for 60 years; at station D, for 80 years; and at station E, for 50 years; the aggregate of the period of records or sum being 300 years. Treating this aggregate as a single record for the area under consideration, it may be said by the above definitions of frequency, that the highest rainfall intensity recorded in the entire period has occurred with a probable frequency of once in 300 years."

The most important words in this description are "located within an area possessing uniform rainfall characteristics." Too many studies have been made in which the writers have totally lost sight of this qualification, and the authors appear to have given little consideration to this requirement when they combined in their studies the records of stations as far apart geographically as Boston, Mass., Dodge City, Kans., Knoxville, Tenn., and Yankton, S. Dak. The topography and climatological conditions affecting quantities and intensities of rainfalls within this wide area vary so much that there is grave doubt whether a combination of the records is of any significance whatever.

Indeed, it may be noted that stations located only a few miles apart may be subject to such different conditions that it would be distinctly improper to combine the records. For instance, data relating to rainfall intensities at the summit of Mt. Washington, in New Hampshire, and at a point perhaps not more than 20 or 30 miles distant at a much lower altitude, certainly should not be combined. It is questionable also how far the records of several stations located within a district measuring not more than 10 to 15 miles in any direction should be combined in any analysis of frequency. Records from such gages are of great importance in studying the extent of the area covered by intense rains[20]; but that the records of ten such gages which have been maintained for 10 yr could be of equal value to a similar record of a single gage for 100 yr in any study of frequency, obviously is impossible.

---

[19] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

[20] "The Distribution of Intense Rainfall and Some Other Factors in the Design of Storm-Water Drains," by Frank A. Marston, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 535.

Another item which is fully brought out in the foregoing quotation, but perhaps not emphasized as much as it should be, is that the record at each of the stations from which data are proposed to be combined, should be of considerable length. The typical example quoted relates to five stations, with a least period of record of 40 yr. Granted that the topographical conditions are such that rainfalls of like frequency and intensity may occur at each of these several stations, there can be no question that the combined record of the five stations is of much more value than that of a single station. If, however, the combined record totaling 300 yr in the example given, were based on 50 stations having an average length of record of 6 yr per station, and perhaps ranging from 1 yr to 20 yr at the different stations, the combined record would be of little greater value than that of the single station having the longest record.

A paper[21] presented by the late David L. Yarnell, M. Am. Soc. C. E., which was issued in 1935, contains a much more extensive analysis of Weather Bureau records of intense precipitation than that shown by the authors, and appears to be of distinct importance. Mr. Yarnell stated: "The methods followed and the results obtained differ considerably from those of the Miami Conservancy District."

The importance of meteorological cycles must not be forgotten in any study of this kind. In this discussion the term, "cycles," is used without particular reference to its precise applicability. Whether or not changes of meteorological conditions occur with such regularity that they may properly be called cycles, there can be no question that wide differences of climatological and meteorological conditions have occurred within historic times. For the purposes of this discussion it may be considered that what is herein called a "cycle" probably has a duration of not less than 300 yr and may be as long as 1 000 yr. Any combination of the records from a number of stations, which have been obtained in the years during the part of a cycle when the rainfall is either high or low, cannot be accurate when consideration of frequencies of 300, 500, or 1 000 yr is discussed.

With regard to the type of formula which may best represent the relation between intensity of rainfall and its duration, for any given frequency, the authors state that the form, $i = \frac{A}{t + b}$, was found to be best. It might well have been noted that the form,

$$i = \frac{A}{(t + b)^d} \qquad \text{(29)}$$

would be a more satisfactory form and one applicable to all attempts thus far made, of which the writer has knowledge, to express this relation by a formula. If the exponent, d, is unity, Equation (29) is identical with

---

[21] "Rainfall Intensity-Frequency Data." *Miscellaneous Publication No. 204*, U. S. Dept. of Agriculture.

Equation (3). If, at the same time, the value of b is 0, Equation (29) conforms to Professor Nipher's formula of 1885 for St. Louis, Mo. If b has a value of 0 and d a value differing from unity, the formula corresponds to that used by the writer[22] in 1905; and if b has a value other than 0 and d a value other than unity, the formula would correspond to that used by the writer[23] in 1931.

Conclusions (6) and (7) of the paper might perhaps have been considerably modified after consideration of the discussion in Mr. Marston's paper.[20] It appears probable that the data studied by the authors might have been analyzed by the methods suggested by Mr. Marston so as to provide information of great value regarding the variations in rainfall intensity over areas of moderate size.

GLEN N. COX,[24] ASSOC. M. AM. SOC. C. E. (by letter).—Many data have been presented very ably in this paper, which should make possible closer predictions as to expected rainfall rates for any mid-western section. Nevertheless, it raises certain questions as follows: The U. S. Weather Bureau standard recording rain-gage is a tilting bucket type. Gages of this type are able to operate at a certain maximum rate due to the inertia of the parts and will not record correctly excessive precipitation. The readings given by the record chart are low. This under-recording will begin when the intensity exceeds about 3.5 in. or 4 in. per hr. Then it becomes necessary to distribute any difference between the stick measurement and the chart value by empirical methods. The last sentence of the first paragraph under the heading "Stations Studied" reads: "No correction factor was used for the precipitation corresponding to any duration." In Table 4 (*a*), three occurrences of precipitation between 0.70 and 0.79 in. are listed. These values correspond to an intensity of about 9 in. per hr which is truly of cloudburst proportions and one which a gage of the tilting type can not record accurately. For this reason, one wonders as to the exact meaning of the foregoing quotation.

Some consideration should have been given to the time of year when certain rates could be expected. After all, the engineer is only interested in precipitation intensities inasmuch as certain run-off rates follow. Many factors other than rainfall intensity affect the run-off rate. For any one water-shed, the time of year, the temperature, extent, and condition of vegetation, the condition of the soil, and previous precipitation are very important; and, in addition, the properties of the water-sheds vary greatly. It is entirely possible for a 1-in. slowly falling rain in early spring to cause a greater run-off than a 3-in. dashing rain of midsummer. After all, 1 000 cu ft per sec per sq mile only corresponds to a rate of 1.55 in. per hr. Run-off rates of this magnitude may follow after previous precipitation has saturated the soil and filled the surface storage.

[24] Prof. of Mechanics and Hydraulics, Louisiana State Univ., University, La.

Since April, 1933, the Louisiana State University, in co-operation with the U. S. Geological Survey, under the writer's direction, has maintained a number of U. S. Weather Bureau standard rain cans and one weighing type of recording gage. During this time, data have been obtained which permit the comparisons of Table 15. The number of times that the Weather Bureau designations were exceeded for excessive rates, for the 5, 10, 15, 30, 60, 100, and 120-min intervals, was 3, 11, 17, 17, 8, 1, and 0, respectively. During this period, in spite of the fact that Louisiana is subject to precipitation of cloudburst intensity, the maximum depth for the 5-min period was 0.42 in., which corresponds to an intensity of 5.04 in. per hr. These data show the relative improbability of obtaining the quantities designated by the authors, or by the Weather Bureau, for the short intervals, and also the improbability of obtaining the Weather Bureau's designation for the longer periods.

various equations raises the question of the actual dependability of empirical formulas. In their application it should be remembered that such formulas are reliable only within the range of data from which they are derived. Especially is this true when the mass of data is segregated arbitrarily into periods of durations, as is done in the case of rainfall intensities. Actually, the "picture" presented by such data is the complete regimen of rainfall. Therefore, by considering separately that falling within certain time limits, there is introduced an artificiality which must be taken into consideration when utilizing the results of such a study.

FIG. 14.—MAXIMUM RATE OF PRECIPITATION FOR THIRTY MINUTES.

However, this should not detract from the importance of the study which has been submitted by Messrs. Schafmayer and Grant. Their efforts, although restricted to Chicago, point the way to other investigations which undoubtedly will add to the information now possessed concerning precipitation.

Regarding the use of empirical formulas for sewer design, especially those involving frequency, it is interesting to compare the results with a study of the maximum precipitation for various time-lengths. This, the writer has done for 5-min intervals to include 30 min. Figs. 13 and 14, for example, show maximum rates of precipitation for 5 min and 30 min, respectively.

EUGENE L. GRANT,[26] M. AM. SOC. C. E. (by letter).—An implied conclusion of this study is that the intensities and frequencies of extreme storms of short duration do not vary greatly over a large area of Central United States. Although the area bounded by a line passing through St.

---

[26] Associate Prof. of Civ. Eng., Stanford Univ., Stanford University, Calif.

Paul, Minn., Detroit, Mich., Knoxville, Tenn., Memphis, Tenn., Dodge City, Kans., and Yankton, S. Dak., contains wide variations in annual rainfall and other climatic characteristics, it is apparently homogeneous with respect to the frequencies of the intense storms which were studied. This implied conclusion should interest all students of meteorology and hydrology; it is of immediate practical importance in that the curves in the paper—particularly the very useful Fig. 5—may be applied to the economic design of storm drains throughout this entire area.

Because of the importance of this conclusion, and because the combining of a 33-yr record for ten stations into what amounts to a 330-yr record seems to be justified only on the assumption that the storms at each station are independent events which are subject to the same system of chance causes, it is desirable to check this conclusion in all possible ways. One such check was the observance by the authors of the close correspondence between the (unpublished) graphs for the individual stations. Other checks may be devised which make use of the methods of mathematical statistics, and which give results expressed in terms of probability. Two types of tests of this character which have been made by the writer seem to confirm the conclusion that the observed differences between the ten stations studied in detail are such as might be expected as chance variations in samples of the size observed, if there were no variations in the cause systems affecting the ten stations.

The first of these tests is the so-called χ^2 test of goodness of fit devised by Karl Pearson and elaborated by Mr. R. A. Fisher[27] which has been applied to each of the seven sections of Table 4. A sample calculation relative to the 30-min storms of Table 4(d), is shown in Table 16, in which

---

[27] A general explanation of this test may be found in "Probability and Its Engineering Uses", by T. C. Fry, Articles 102–104. The specific application to a problem of the type presented in testing Table 4 for homogeneity is based on unpublished notes on "Statistical Inference", by Prof. Harold Hotelling, of Columbia Univ., New York, N. Y.

f_o = number of storms of a given magnitude observed at a given station in the 33-yr period; and f_e = number of storms expected, assuming uniform conditions.

The χ^2 test involves the classification of the observed data into groups or "cells"; the number expected in each cell according to the hypothesis to be tested is then computed. In this case the hypothesis is that all the ten stations are alike with respect to the occurrence of intense storms of each magnitude, so that the number expected at each station is the average number of storms observed at the ten stations for each precipitation. The departure from expectancy in each cell is then squared and divided by the number expected in the cell; the sum of these computed values is called χ^2. Probability theory then gives the relation between χ^2, the number of "degrees of freedom" (the total number of cells compared minus a correction for the number of ways in which the numbers expected are made to agree with numbers observed), and the probability, *P*, that if the expected system of causes were really operating, a departure from the expected number as great as, or greater than, that observed would occur as a matter of chance in random sampling. The purpose of the test, of course, is the determination of this value of *P*.

In Table 16 it has been necessary to group together all storms in excess of 1.20 in. at each station; experience with the test indicates that it cannot be expected to give satisfactory results if the expected frequency in any cell is fewer than five. A similar condensation of cells has been made in testing each section of Table 4.

Table 16 gives a χ^2-value of 37.1. There are 36 degrees of freedom, 40 cells minus 4 restrictions imposed by the condition that the total number expected in each precipitation group agree with the total number observed in that group. Entering a table of χ^2-values, such as may be found in many books on statistical methods,[28] these two values give a probability, *P*, of 0.4. This is interpreted to mean that if there were no real difference in the cause systems affecting 30-min excessive storms at the ten stations, a variation from uniform results as great as or greater than, that observed might be expected four times out of ten. In other words, the observed data are not inconsistent with the hypothesis of uniformity. The results obtained from χ^2-tests on the other sections of Table 4, are shown in Table 17; they seem to confirm this conclusion. The best fit to the assumption of uniform causes is found in the storms from 60 to 120 min in duration.

The second statistical test made by the writer involved the checking of an hypothesis concerning the relation between the average number of excessive rainfalls per year of each duration, and the probability of any given number of such excessive rainfalls occurring in any single year. This hypothesis is that this probability may be determined by the Poisson law[9], which expresses the probability of any given number of occurrences per period as a function of the average number of occurrences, m. The Poisson law gives the probability of no occurrences as e^{-m}, of exactly one occurrence as me^{-m}, of exactly two as $\frac{m^2}{2} e^{-m}$, of exactly three as $\frac{m^3}{3 \times 2} e^{-m}$, of exactly four as $\frac{m^4}{4 \times 3 \times 2} e^{-m}$, etc.

* Not determined.

The characteristics of extreme rainstorms would seem on theoretical grounds to agree with the assumptions underlying the Poisson law, at least in so far as the rainstorms at any one station are concerned. In brief, these assumptions are that the quantity measured is the number of occurrences of a particular event, each sample consisting of a very large number of independent trials of the event in which the probability of the event occurring on any individual trial is very small. Extreme storms are presumably independent events; there are a great many short intervals of time during a year which might have such storms; the probability of an extreme storm in any one of them is very small indeed.

In testing the Poisson law hypothesis it was necessary for the writer to examine the original rainfall data assembled by Messrs. Schafmayer and Grant in order to construct frequency distributions which showed in how many station-years there were no excessive storms of a given duration, and in how many there were one, two, three, four, etc. The expected number of years which would have each number of storms was then calculated by the Poisson law, using the observed average. Table 18 gives the data for the storms of 10-min duration, and illustrates the method followed. Dividing the total of Column (3) by the total of Column (2), the average number of storms per year, m is found to be $\frac{396}{330} = 1.20$; $e^{-m} = 0.3012$; $me^{-m} = 1.20\ (0.3012) = 0.3614$; $\frac{m^2}{2} e^{-m} = \frac{1.20}{2}$ $(0.3614) = 0.2168$; $\frac{m^3}{3 \times 2} e^{-m} = \frac{1.20}{3}\ (0.2168) = 0.0867$; etc.

---

[9] For mathematical derivations and discussions of the Poisson law, see Fry's "Probability and Its Engineering Uses", Articles 83-88. For examples of a number of other series which are fitted by the Poisson law, see "Applications of Poisson's Probability Summation", by Frances Thorndike, *Bell System Technical Journal*, Vol. 5 (1926), p. 604.

It will be noted that the number of 10-min storms shown in Table 18 for the 330 station-yr is necessarily the total of 396 shown in Table 4(*b*) for the same station-years. The correspondence between the observed frequencies shown in Column (2), and the theoretical frequencies from the Poisson law shown in Column (5), is extraordinarily good. Similar checks between observed and expected values—although not quite as close as this one—were found for the frequency tables for the storms of other durations. The χ^2-test was used to compare these observed and expected frequencies; the values of *P* obtained from these tests are included in Table 17.

TABLE 18.—POISSON LAW FITTED TO NUMBER OF 10-MINUTE EXCESSIVE STORMS PER STATION-YEAR

Number of excessive storms *N*, in year (1)	Observed number of station-years with exactly *N* storms, *f* (2)	Total storms in each group *fN* (3)	Probability of exactly *N* storms by the Poisson law (4)	Expected frequency in 330 station-years by the Poisson law (5)
0..............	102	0	0.3012	99
1..............	114	114	0.3614	119

4..............	10	40	0.0260	9
5..............	2	10	0.0062	2
Totals..............	330	396	......	330

It would seem reasonable that the relationship herein discovered between the average number of storms per year of a given magnitude and duration, and the probability of any given number of such storms occurring in any one year, justifies the use of the Poisson law for similar calculations relative to extreme storms of any frequency. For instance, any storm shown on Fig. 5 with a frequency, *F*, of 5 would correspond to an average of 0.2 storm per yr. The probability of no such storms in any one year may be computed by the Poisson law to be 0.819, and of exactly 1 yr to be 0.164; thus, in only 17 yr out of 1 000 would two or more such storms occur in the same year. Such computations would seem to be more of academic than of practical importance, although they might afford a kind of doubtful comfort to the engineer who has just seen his storm sewers overflowed by one such storm.

The important practical conclusion from the Poisson calculations is that they furnish another check on the hypothesis that the excessive storm characteristics are the same at all of the ten stations studied. It is a mathematical property of the Poisson law that two or more Poisson distributions with different averages do not add up to make another Poisson distribution; thus, the check between the total results for the ten stations and the Poisson law is good evidence of similarity between the stations.

The points of similarity and the fundamental differences between this study of rainfall intensity, and the many interesting studies which hydraulic engineers have made of flood frequencies, are worthy of comment. Although the authors have made use of no "probability curves" such as have been used in many flood studies, the same general philosophy underlies the approach to both problems. The evident fact that the authors' studies of excessive rainfall frequency seem much more conclusive than any published studies of flood frequency, results from certain characteristics of the rainfall problem which are not found in the flood problem. These advantages may be recognized if the implications of a frequency or probability approach to a problem of this type are noted.

The statistical or frequency definition of probability may be stated as follows: Assume that if a large number of trials of an event are made under the same essential conditions, the ratio of the total number of trials in which a certain event happens, to the total number of trials made, will approach a limit as the latter number is increased indefinitely; then the limit thus described is defined as the probability that the event shall happen under these conditions.

In the flood studies such as those made by the late Allen Hazen,[30] M. Am. Soc. C. E., the trial may be thought of as a year; the event which either happens or fails to happen is a flood of a given magnitude. Several assumptions are made, either consciously or by implication, in flood studies leading to probabilities for floods of any given magnitude. Among them are: (1) There really is a natural law which relates to the probability of a flood of a given magnitude at a given point on a given stream at a particular time; if it were possible to secure records for a great many years during which time there was no fundamental change in climate or in the characteristics of the stream's drainage area, the ratio of occurrences of a given flood to total years would actually approach a statistical limit; (2) successive trials are made under the same essential conditions or nearly enough so for practical purposes; this implies among other things that they are independent of one another; that is, the flood magnitude in one trial is not related to a flood magnitude in preceding or succeeding trials; and (3) there is a definite relation between the probability or frequency of a flood of given magnitude and the magnitude of the flood, which relationship would be apparent if one had a sufficiently long record. On the basis of a limited record an attempt is made to fit some kind of probability curve to the available data, extrapolating if necessary in order to obtain desired probabilities. Thus, it is common for investigators using these methods to calculate the probability of the 1-yr-in-100 flood from a 30-yr record—or sometimes even the 1-yr-in-10 000 flood.

The logical weakness of such extrapolation beyond the limits of a poorly defined frequency curve is obvious. Different forms of curves may seem to fit the limited data fairly well, and yet have widely different implications outside its range when they are used as a basis of extrapolation. Thus, the methods developed by different investigators of flood frequencies give very different results when applied to the same problem. One investigator may designate as a 1-yr-in-57 flood what another calls a 1-yr-in-500 flood.[31]

---

[30] "Flood Flows", by Allen Hazen, John Wiley & Sons, 1930.

[31] See the discussion by C. S. Jarvis, M. Am. Soc. C. E., in *Proceedings* Am. Soc. C. E., Papers and Discussions, October, 1927, p. 2028, for this particular example. The wide differences in conclusions obtained by different methods of extrapolation are familiar to any student of this subject.

Two attempts have been made by investigators to avoid extrapolation by increasing the data used from a limited number of years of record. One method has been to combine the records for a number of streams; the other has been to take all the flood peaks each year in order to obtain a great many floods from a record of short duration. Neither of these devices seems reasonable with respect to flood probability studies. The water-shed characteristics of the various streams are sufficiently different so that floods on separate streams are not under "the same essential conditions;" the successive floods on a given stream in a given year are certainly not independent events.

In studies of intensity and frequency of excessive rainfall, however, it does seem reasonable to use both these devices. As was evidenced by the application of the χ^2-test to the data in Table 4, the excessive rainfalls of short duration at widely separated stations seem to come from the same system of chance causes. Excessive rainstorms are local in character; the storms at different stations at a considerable distance from one another are obviously independent events. Thus, it is legitimate to combine the 33-yr records of ten stations to secure what in effect is a 330-yr record.

It also seems reasonable in these rainfall studies to make use of all the excessive storms that have occurred in a given year. Although two or more flood peaks in a year on the same stream would seem to be definitely related, two or more excessive rainstorms of short duration in the same year at one station might be expected to be completely independent. This expectation is confirmed by the close fit of the number of storms per year to the Poisson law.

Finally, the investigator of the frequencies of excessive rainfalls who wishes to use his conclusions in the economic design of storm sewers has a great advantage over the investigator of flood frequencies who wishes to use his conclusions in the economic design of structures subject to flood. In theory at least, design for long-run economy of both storm sewers and flood spillways would seem to require consideration of the cost of providing each possible capacity, the expected frequencies with which such capacity would be exceeded, and an estimate of the probable resulting damage. However, the conclusions of economy studies in the two fields, as to the frequencies against which it is economical to design, are likely to be quite different. A typical conclusion might be that a spillway should be designed against at least the 1-yr-in-100 flood, whereas a storm sewer should be designed, at most, against the 1-yr-in-5 excessive rainfall. In the first instance extrapolation to estimate the 1-yr-in-100 flood from a record of 30 yr or less involves much guesswork as to the form of the frequency function. In the second instance, as the authors have demonstrated, a 330-yr record defines its own frequency function so that it is possible to estimate the 1-yr-in-5 rainfall with a high degree of confidence, and there is no necessity for extrapolation.

ADOLPH F. MEYER,[32] M. AM. SOC. C. E. (by letter).—This paper gives encouragement to those who have labored long in favor of the use of station-year records from a relatively large area in preference to the present-day inadequate records of intense precipitation at a single station, for the purpose of predicting rainfall frequency. The fundamental soundness of the method of determining frequencies from station-year records is demonstrated by the fact that, notwithstanding the recent severe droughts, the last eighteen years of rainfall records (1929-37), when added to the earlier nineteen years of record for stations analyzed by the writer elsewhere,[33] do not result in any material change in the conclusions respecting the frequencies of given rates of intense precipitation to be expected in the several time intervals from 5 min to 2 hr.

---

[32] Cons. Hydr. Engr.; Engr. (Meyer Governor Co.), Minneapolis, Minn.

A comparison of the frequency of intense precipitation, as determined from the authors' graphs in Fig. 3, for 659 station-yr, with the frequency of the same rates of intense precipitation for the City of Chicago, Ill., taken from charts presented by the late David L. Yarnell, M. Am. Soc. C. E.,[34] is most striking. The values are almost identical, with the exception of the 100-yr, 2-hr rate shown in Fig. 3 of the paper. It is the writer's judgment, however, that curves, and not straight lines, should be used to represent the actual facts shown by the observational data in Fig. 3. If curves are used, the 2-hr precipitation of 100-yr frequency is substantially reduced and comes into much better agreement both with the Yarnell charts and with the writer's formulas, first published twenty years ago.[35]

The writer has found further satisfaction in the authors' use of definite rates of precipitation for the various time intervals as measures of what constitutes "excessive rainfall" rather than the use of percentages of annual rainfall. It has always been the writer's contention that there is no material relationship between intense precipitation during short-time intervals and annual precipitation. Stations with low annual precipitation are quite likely to have very intense precipitation for short-time intervals, although the frequency of such excessive rainfalls is usually greater in regions of moderate and heavy rainfall.

Another point cited by the authors which is worthy of emphasis is the fact that the maximum rainfall determined from the original rainfall recording gage charts for any given time interval is greater than the maximum determined from the published tabular data. The writer has called attention to this fact[35] in analyzing approximately 300 storms for Minneapolis and St. Paul, Minn., with a view to determining the correction which should be applied to the tabular data published by the U. S. Weather Bureau. The data published for Minneapolis and St. Paul give results 9% too small for the 5-min interval, 11% too small for the 2-hr interval, and from 2 to 4.5% too small for the intermediate intervals from 10 min to 60 min. These errors of about 10% for the 5-min and 120-min intervals are far in excess of the differences between conclusions drawn from the writer's 19-yr record,[33] as compared with those drawn from the present 37-yr record.

---

[33] "The Elements of Hydrology", by Adolph F. Meyer, 1917, Group 3, p. 198.

[34] *Miscellaneous Publication No. 204*, U. S. Dept. of Agriculture.

[35] "The Elements of Hydrology", 1917, p. 165.

Another fact which bears emphasis, because of a deficiency in the earlier published data of the Weather Bureau and of errors frequently made by those who use such data, is that the accumulated precipitation for 60 or 80 min, for example, must also be considered as having fallen in 100 and 120 min, even if the rain did not continue that long, or was not excessive toward the end and, therefore, was not reported. Where the rain did continue, but the rate was not excessive, the later records of the Weather Bureau now give the necessary information.

Most of the questions to which attention has been directed herein result in increasing the quantity of rain which may be expected in a given time interval. If designs are to be conservative, these several factors must be taken into consideration.

When it is noted that the formula heretofore used in Chicago gave frequencies varying from 3 to 20 yr, which were supposed to represent approximately 5-yr frequencies, it must be apparent that the adoption of new values of frequencies for given rates of intense precipitation will result in better balanced and more economical sewer designs for the City of Chicago.

The writer believes that the Yarnell charts,[34] are by far the best measure of the frequency of given rates of intense precipitation over most of the United States, available to-day.

CLINTON L. BOGERT,[36] M. AM. SOC. C. E. (by letter).—A very complete study of rainfall intensities is reported in this paper. The authors have extended the analytical methods of comparing rainfall intensities and frequencies.

In pursuing statistical methods, engineers should not become so engrossed in the formulas and curves derivable from the data at hand, as to lose sight of the ultimate aim of the study, which is to obtain the run-off from a given area under the worst conditions.

This run-off is dependent on two factors of about equal weight, namely, the rainfall intensity with which this paper is concerned, and the run-off factor. Assuming that the studies are being made to establish the size of drains, the drains will be improperly proportioned if an error in judgment is made in selecting either of the factors. The run-off factor depends upon the slopes and the extent of the built-up and paved areas in the drainage district. Zoning will tend toward making this factor slightly more determinate, but there is no telling when, in the future, Court or legislative action will alter zoning restrictions and automatically put the engineer's assumptions of the future character of the district awry.

Another variable in the problem is the frozen ground in winter which is not considered in arriving at a run-off coefficient. A snow-covered lawn with an ice glazing is equivalent in run-off capacity to a paved area. In most cases of inadequate drains, the flooding will be found to occur in the early spring, due to high run-off from frozen ground and glazed snow.

[36] Cons. Engr. (Sanborn & Bogert), New York, N. Y.

C. H. EIFFERT,[37] M. AM. SOC. C. E. (by letter).—The writer is very much interested in this paper and is pleased to note that the authors apply the method of combining years of record of a number of stations to be used in the determination of frequencies. This method was used extensively in one of the Technical Reports of the Miami Conservancy District, "Storm Rainfall of the Eastern United States", published in 1917. This report was revised and reprinted in 1936. Elsewhere,[38] the writer has attempted to emphasize some of the possibilities of this method for increasing the usefulness of precipitation records of comparatively short duration. The Miami Conservancy District studies were of great storms lasting from 1 day to 5 days and were made for flood-control purposes, whereas the investigations described by the authors were made in connection with sewer design and refer to excessive precipitation lasting from 5 min to 2 hr. However, the principle of combining the years of record is the same.

It is perhaps pertinent to state that judgment and caution must be used in the application of this method. The area from which the records are combined must have uniform rainfall characteristics; otherwise, the results will not be correct for different points within the area. For instance, an area in which there are great differences in altitude would probably also have great differences in precipitation both as to type and quantity. The years of record for stations in such an area could not be combined satisfactorily.

The records for the individual stations should be long enough to cover a fairly complete rainfall cycle. Such cycles are indefinite at best; yet it is well known that periods of wet and dry years do occur. Therefore, any record so short that it covers a wet or a dry period only would not be suitable for use in this connection.

In the aforementioned work of the Miami Conservancy District, the eastern half of the United States was divided into 2° quadrangles. The records of the stations in each of these quadrangles were added to obtain the total years of record for the quadrangle. Records of less than 5-yr duration were discarded. The size of the quadrangles used is somewhat arbitrary. It should probably be changed in order to obtain the most satisfactory results for certain localities. In the study of the entire eastern half of the United States this refinement could not be attempted on account of the work involved.

There seems to be no good reason for combining the records of stations as far apart and differing as much in climatic character as Boston, Mass., Yankton, S. Dak., and Knoxville, Tenn. The combination of records from stations in the Chicago (Ill.) area should be quite satisfactory. It is true that the records of a number of the stations are much shorter than is desirable so that only part of a cycle is covered and this fact should be borne in mind when the data are being used. Even if the period is short it is probably the best possible way of using these records. It will be necessary to revise the curves from time to time as records accumulate.

---

[37] Chf. Engr. and Gen. Mgr., The Miami Conservancy Dist., Dayton, Ohio.

[38] *Engineering News-Record,* December 31, 1936.

A very valuable publication on "Rainfall Intensity-Frequency Data", by the late David L. Yarnell, M. Am. Soc. C. E., was issued by the U. S. Department of Agriculture in August, 1935. This record covers periods from 5 min to 24 hr. The values taken from the authors' curves for Chicago agree very closely with those for the same location taken from Mr. Yarnell's maps.

The writer has seized every opportunity in the past to emphasize the necessity for obtaining more complete records of rainfall and run-off, and cannot refrain from doing so again in this connection. The U. S. Weather Bureau needs many more recording rain-gages. The records should be made continuous and should not be subject to termination on account of lack of appropriations as they are at the present time. Fragmentary records lose a great deal of their value for the aforementioned reason, namely that they cover only parts of cycles. Engineers should emphasize the importance of such records whenever possible because legislators, as a rule, do not realize the necessity for them.

C. S. JARVIS,[39] M. AM. SOC. C. E. (by letter).—The persistency of the straight-line relations as shown in Fig. 2 is so striking as to invite further consideration. It is found that the data included in Meyer's Table 15, Groups 2, 3, and 4,[40] conform moderately well to straight lines for the lower rainfall intensities (Fig. 15). However, for Group 1 the divergence of the data from straight-line trends becomes quite marked, thus requiring the use of irregular curves. Similar divergence from the straight-line relation is apparent likewise in the data furnished for Boston, Mass., by Charles W. Sherman,[41] M. Am. Soc. C. E., and re-plotted on semi-logarithmic paper in Fig. 16(*a*).

When the data from Group 3 of Meyer's Table 15 were plotted similarly on the same scale as that used for Fig. 2 of the paper, their inclination to fall on straight lines was quite pronounced; but when plotted on a much larger scale, the divergences became proportionately more apparent.

Approaching the problem independently, the writer undertook to analyze the excessive precipitation data[42] for Indianapolis, Terre Haute, Evansville, Fort Wayne, and Royal Center, in Indiana; Cleveland, Columbus, Dayton, and Cincinnati, in Ohio; Pittsburgh, Pa.; St. Louis, Mo.; and Chicago, Ill., representing a total of 301 yr of record, or an average of 25 yr per station, the maximum record period being about 34 yr for Indianapolis, with 33 yr for Pittsburgh, Columbus, and Cincinnati. The resulting intensity-frequency graphs are shown in Fig. 16(*b*), on which the data from 301 station-yr of composite record are summarized graphically, all conforming more or less closely to straight-line trends.

Fig. 17 provides a graphic comparison of rainfall frequency-intensity trends for Cincinnati and Chicago, and indicates somewhat higher intensities for Cincinnati, except for 5-min periods, when the graph follows an irregular curve, crossing the straight-line trend for Chicago.

Whether the data from 12 stations, representing an aggregate record period of 301 yr, may be regarded and analyzed as a continuous record at one station for three centuries has never been settled authoritatively, although the assumption has been widely accepted. Valuable generalizations, trends, and conclusions have been derived from such composite records; but, thus far, no one has claimed and proved their equivalence to continuous records of equal lengths from single stations. Neither has it been established satisfactorily that straight-line relations inherently exist among observed hydrologic or other physical data, no matter what scale or form of chart is used. The natural inequalities and irregularities appearing in practically all basic data must be "ironed out" by some selective grouping, averaging, or other leveling process, or by plotting on small-scale charts, before the inherent deviations from the trend lines or curves are practically eliminated, or reduced to significant, readily understandable quantities, susceptible of logical interpretation.

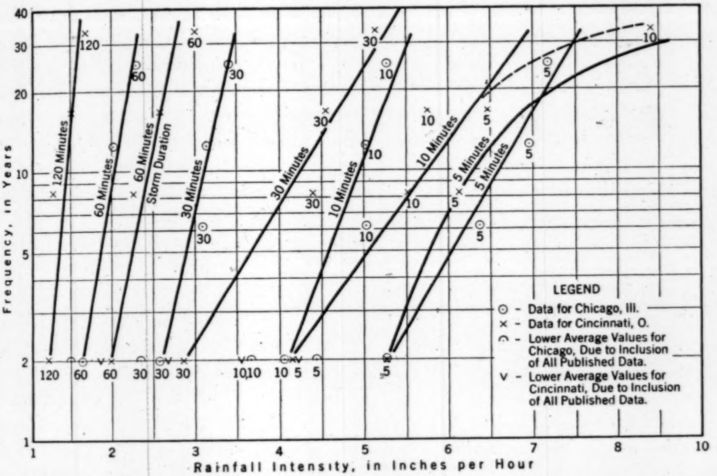

FIG. 17.—COMPARISON OF RAINFALL FREQUENCY-INTENSITY RELATIONS FOR CINCINNATI, OHIO, AND CHICAGO, ILLINOIS.

The writer has been unable to reconcile the various trends of Fig. 2, whereby the rainfall intensities for given frequencies become slightly less severe as the station-years increase, although the added stations are supposed to be fairly comparable. One would naturally expect higher records to be developed as stations are increased in number and as the record periods are extended.

The authors have made important contributions to the subject of their paper, and have apparently established a safe basis for the design of storm sewers in the Chicago District.

A. J. SCHAFMAYER,[43] M. AM. SOC. C. E. (by letter).—The constructive type of discussion submitted brings out some interesting points. For example, Mr. Cochrane's comparison of Equations (18) and (27) in Table 8 shows a very remarkable agreement in intensities.

---

[43] Engr., Board of Local Impvts., City of Chicago, Chicago, Ill. Mr. Grant, co-author of this paper, died on October 30, 1936.

Mr. LeRoy K. Sherman questions the grouping of the Tennessee stations with the others included in the Chicago group. As pointed out by Professor Meyer, the writers are in agreement with his deduction that there is no material relationship between the intense precipitation for short periods of time and the quantity of annual rainfall.

As to Mr. Sherman's question: Are irregularities "ironed out" for small urban areas? the writers' study of the data led them to believe that irregularities are "ironed out" for areas requiring a time element of 15 min, or more, for excessive intensities. However, this may not be true for annual quantities, as shown by George W. Pickels,[44] M. Am. Soc. C. E. The writers made no attempt in this study to relate intensity and run-off or to secure simultaneous intensity and run-off data, as was done in the study by Messrs. Horner and Flynt.[13] It is evident, however, as stated by Mr. Sherman, that the intensity rates may be applied to run-off computation by the so-called rational method, or by the Sherman unit hydrograph[11, 12] method, or by empirical graphs, or tables of other types. Table 9, submitted by Mr. Sherman, shows the value of careful study in this part of the design.

In his studies of rainfall for Kansas, Professor Jones presented some interesting data. As he states, however, comparisons, especially with his ogive curves, are difficult. Although their studies led the writers to believe that the quantity of annual rainfall has no relation to the intensity for short durations, it appears that this is true only for the excessive rates with a high minimum intensity used by them, as shown under the heading, "Definitions of Terms." If lower intensities are included and a large number of storms of minor intensity are added to the tabulations, the principle of independence between intensity and annual precipitation is modified, and this independence tends to decrease as the minimum rate is reduced. For example, in Section (*a*) of Table 11, the occurrences listed by Professor Jones with intensities less than that used by the writers, number 1 077 in a total of 1 243 items, or more than 86%; but even with this increase in number of occurrences, the data as shown by the analysis of Professor Jones may be statistically comparable. Although such storms of minor intensity are of great importance from the standpoint of storage for agricultural or hydro-electric purposes, etc., they are of slight importance in the design of storm sewers and were not considered by the writers. The stations used were selected on the basis of the uniformity in the recorded data as shown in Table 4.

In Fig. 12 Professor Jones presents a chart showing the quantity-intensity relationship, since multiplying intensity by time gives the quantity or accumulated depth. The use of minutes in multiplying in this particular case gives a function of the quantity instead of the actual depth, but the ratio is constant. Professor Jones shows clearly the variations of the records of single storms from the Talbot type of formula. The writers also found that records of single storms showed considerable variation from the formula. However, the averages of a great many records of high intensity appear to fit very closely.

---

[44] "Run-Off Investigation in Central Illinois," *Bulletin No. 232*, Eng. Experiment Station, Univ. of Illinois, pp. 91–93.

Mr. Charles W. Sherman brings up an important point. Geographical and topographical influences undoubtedly affect rainfall. The stations used, however, showed, by recorded data, a similarity of occurrences of high intensity under the existing geographical and topographical variations. It is as conceivable that several places more or less remote from each other should have similar rainfall intensity and frequency characteristics in the excessive range, while differing greatly in total annual rainfall, as that several such places might have the same altitude, even if hundreds of miles of mountains and valleys separate them geographically. The writers realized that the stations used are not "located within an area possessing uniform rainfall characteristics," as far as total annual rainfall is concerned. They believed, however, that these stations have very similar characteristics in the range of excessive intensities used in their investigations.

Meteorological cycles were considered in this study, but no attempt was made to determine the effects of such cycles except to assume that the data for the 659 station-yr and the 330 station-yr studies include approximately three complete registrations of the common or sun-spot cycle (in so far as it affects the high intensities considered). As to cycles of the order of hundreds of years, the writers agree with Mr. Sherman that the station-year method gives no indication of the effect of such cycles. More years of scientific recording than are now available will be necessary to determine their effect on rates of rainfall.

Conclusions (6) and (7) were based on the studies for the published paper and on unpublished studies of storm patterns which Mr. Grant had been making for some years prior to his death and which were somewhat similar to the studies by Frank A. Marston,[20] M. Am. Soc. C. E., referred to by Mr. Sherman. Because the Chicago gages are spaced irregularly and some are considerable distances apart, only fragmentary storm maps were secured in many cases. Only a comparatively few closed isohyetals near the storm centers could be developed, and most of the storms appeared to be much more irregular in shape and movement than those reported by Mr. Marston. Because these studies were incomplete, it was decided not to include them in the paper as presented. Therefore, no reference was made to the paper[20] by Mr. Marston. However, since this aspect of the general rainfall problem was noted in Conclusions (6) and (7), perhaps such a reference should have been made.

The inaccuracy of the tilting bucket type of record for very high intensities is pertinently noted by Professor Cox. Undoubtedly, the under-recording occurs principally during the periods of very high intensities. The statement quoted that "no correction factor was used for the precipitation corresponding to any duration", means that the writers applied no correction factor in using the published records. Wherever local observers, in preparing rainfall data for publication, may have distributed an excess, as shown by stick measurement over the automatic record, such distribution or correction, of course, was included in the published records, and was used by the writers. No study was made to determine the extent of such correction or distribution and no special consideration was given to it except to mention it in Item (*d*) under the heading, "Deficiencies in Data." A study was made for the Chicago District to determine the time of year when excessive rates occur. A chart showing these occurrences and their dates is included among the unpublished papers, and it can be summarized by stating that all the excessive rates for this District occurred between May 1 and October 21. The comments of Professor Cox as to the conditions affecting run-off, other than the rainfall rate, apply more directly to suburban or rural areas. In metropolitan sewer districts with large proportions of impervious areas those other factors have diminishing influences on the rate of run-off.

Mr. Drummond's charts, shown in Figs. 13 and 14, supply interesting information and should aid an engineer in determining whether the results of these studies can be applied to his local problem.

The statistical analyses of the results of these studies presented by Professor Eugene L. Grant, provide tests of validity of a different type than any considered by the writers. It is gratifying to note that they qualify under such tests. The important implication, as emphasized by Professor Grant, and again by Professor Meyer, is that, within the high intensity brackets used in these studies, stations many hundred miles apart and with dissimilar annual rainfall characteristics have similar frequency-intensity characteristics.

Mr. Bogert emphasizes the run-off factor in the final design of sizes and capacity of drains. The writer agrees with Mr. Bogert that these studies dealt with only one of the elements concerned. However, the determination of run-off is another step that requires a specific consideration of the items enumerated by Mr. Bogert for the particular locality as well as a considerable element of judgment.

The statement by Mr. Eiffert that judgment and caution should be used in applying the station-year method is undoubtedly true. It was the opinion of the writers, however, that the similar characteristics for the high intensities shown in the data assembled in their studies as well as in the studies by Meyer[4] justified using the stations selected. Mr. Eiffert's comments as to cycles as well as those of Mr. Charles W. Sherman are quite correct. Although the 19-station and the 10-station series in the paper include approximately three of the sun-spot cycles, they cannot show the effect of long-term cycles. Some of the older local stations and the two Chicago stations of the U. S. Weather Bureau, in the Chicago District series show more than one complete sun-spot cycle. The newer stations in Chicago are of such recent date that they do not cover even one of these cycles, as noted in the paper. It is very probable that further accumulation of local records will alter the local data somewhat. The writers were in complete agreement with Mr. Eiffert as to the need for more complete rainfall records.

As stated by Mr. Jarvis, the straight-line relationship is more apparent in some cases than in others. The writers noted, however, that the divergence appeared to decrease as the quantity of data increased. The variations from a straight line for the Group 1 and Boston data in Fig. 15 and Fig. 16 (*a*) are interesting and worthy of further study. The writers also found the greatest deviations from a straight line in the records of the 5-min and 10-min storms. Although the writers had observed the apparent arithmetical-geometrical progression relationships between the intensity and the corresponding time intervals, their studies were stimulated when the paper by Mr. Jarvis[6] was published in 1930.

Referring to the last part of Table 20, the Weather Bureau standard for excessive rates shown on the top line agrees with the writers' definition on the bottom line. Unless this is a typographical error, there must have been a new ruling since that of March, 1934, shown by the writers in detail, under the heading "New Rule of the United States Weather Bureau for Tabulation of Excessive Rainfall." The trend mentioned by Mr. Jarvis indicated in Fig. 2 may be partly due to the method followed by the writers. The 19-station series was developed first. Then the Chicago District was studied and tabulated, using the Weather Bureau stations, together with the City and Sanitary District stations. These latter stations included data from some storms of much higher intensities than were recorded on any of the local Weather Bureau records; for instance, the Mayfair gage of the City of Chicago in the storm of July 26, 1932, recorded 3.87 in. in a 2-hr storm, with diminishing intensities on adjacent gages and with only 1.06 in. recorded for a storm of 1.5 hours' duration at the official University Station of the Weather Bureau about 15 miles away. Hence, the averages for the Chicago District were higher than those for the nineteen original stations. Then, the ten stations whose average data were in closest correspondence with the Chicago data, were selected from the nineteen stations for the 330 station-yr series. This resulted in the averages of the ten stations being higher than those for the entire nineteen stations, but not as high as the averages for the Chicago District.

The study was prompted by the desire to develop a method for using the cumulative data from an increasing number of rain-gages and to investigate the validity of the station-year method of using such data. The recent increase in the number of such gages in the Oklahoma[45] and Ohio[46] studies by the Federal Government may develop still further information on these and other points.

FLOW CHARACTERISTICS IN ELBOW DRAFT-TUBES[1]

By C. A. Mockmore,[2] M. Am. Soc. C. E.

With Discussions by Messrs. F. T. Mavis, Jerome Fee, R. E. B. Sharp, L. F. Harza, Ellery R. Fosdick, Howard L. Cooper, and C. A. Mockmore.

Synopsis

The purpose of this study was to investigate the flow characteristics in the elbow draft-tube, placing special emphasis on the bent part of the tube. The first part of the study consisted of designing and building several different pipe bends and testing them with a Pitot tube for filamental velocities and pressures. Measurements for loss of head were made for various rates of flow to determine which shape of bend offered the least resistance to the flowing water.

The second part of the study involved the design, construction, and testing of several model draft-tubes, patterned after the type of those at the Bonneville Dam, on the Columbia River, in Oregon. The model draft-tubes, as well as the experimental pipe bends, were made of pyralin, a transparent material through which it was possible to take photographs of the phenomena. Motion pictures were made for all conditions of flow in the pipe bends and the draft-tubes.

The tests indicated that the pipe bend which was flattened in the direction of the plane of the bend offered less resistance to flow than any of the other bends, regardless of cross-sectional area. It also appeared that the distance between the inside and outside walls at the outlet of the bend of an elbow draft-tube should be small compared to the throat diameter of the tube.

Introduction

Function of Draft-Tubes.—The draft-tube of a water turbine is an extension of the wheel passages, made so as to perform two principal functions:

Note.—Published in February, 1937, *Proceedings*.

[1] Based upon a thesis submitted to the State University of Iowa in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The data supporting this paper have been filed complete for reference in the Library of the State University of Iowa, Iowa City, Iowa, and in Engineering Societies Library, in New York, N. Y.

[2] Prof. and Head, Dept. of Civ. Eng., Oregon State Coll., Corvallis, Ore.

(1) To reduce the velocity of the water in an efficient manner as it passes through the tube; and (2) to permit the turbine runner to be placed at a convenient distance above the tail-water.

It would be difficult to state which of these two functions is the more important because their relative values may change from one installation to another, depending upon the physical conditions of the plant. Whatever the relative values may be, the total head should not exceed about 25 ft, and this should vary inversely with the specific speed of the turbine, in order that the danger of cavitation may be lessened.

Historical Development of Draft-Tubes.—For those who may be interested in the historical development of draft-tubes, the Appendix will serve as a valuable check list of reading material[8]. In general, they may be divided into two classes: (*a*) Those having straight axes; and (*b*) those having curved axes. This paper presents in detail a study of the flow characteristics in quarter-turn draft-tubes. Draft-tubes with straight axes, mentioned only incidentally herein, have been studied further at the State University of Iowa by Andreas Luksch (6).

The most recent and most complete study of draft-tube literature the writer has been able to obtain was reported in April, 1935, by the National Bureau of Standards (16), of the Department of Commerce, at the request of the Tennessee Valley Authority. According to the report,

"The purpose of this investigation was to examine and report on all published literature on draft-tubes published in English and foreign languages during the past 20 years, to prepare an annotated bibliography of this material, and to make recommendations as to the need for further experiments on draft-tubes, and as to the direction which such experiments should take."

"The current design of draft-tubes," according to the report, "shows a persistent tendency to depart from the use of the spreading and symmetrical types." This is attributed to the better structural features of the elbow draft-tubes and to the improvement in their hydraulic efficiencies. As an example of the findings in improved efficiency for the elbow draft-tube, reference is made to the Lilla Edet (17) experiments in which a "special curved tube, shallow and very long, proved to be superior to the Moody (11) and White (9) tubes at full load performance."

A listing of the recent installations of elbow draft-tubes, such as that given by J. S. Ball (18), seems to vindicate the pioneer work of the late Gardner S. Williams, M. Am. Soc. C. E., who was among the earliest to claim that the elbow draft-tube may have as high efficiency as any other tube built. However, this is not to be construed to mean that the elbow draft-tube will ever entirely displace all draft-tubes having straight axes. No one type of tube could possibly be superior to all other types under all conditions of operation. It was in this connection that Dr. D. Thoma (19) stated: "It is firmly established today that a given draft-tube may be the best possible form for one runner, but not for another. Consequently, the runner and draft-tube should be investigated as a single system."

---

[8] In this paper numerals in parentheses, thus (10), refer to corresponding numbers in the Appendix.

Characteristic Parts of a Draft-Tube.—It appears logical that an elbow-type draft-tube may be considered as composed of three principal parts: (1) The vertical leg; (2) the bend; and (3) the lower leg, sometimes called the horizontal leg.

In the report (16) by the Bureau of Standards, a hypothetical form of draft-tube was assumed as made up of four principal parts for the purposes of discussion. The fourth part was added following the bend, and assumed as consisting of a section of the tube in which there was no increase in cross-sectional area. It appears that this part was added to take care of the suggestion of Viktor Kaplan (13) that in his experiments he found that the addition of such a section had increased the efficiency of the draft-tube. To the writer it appears that this is merely a part of the bend, or should be considered as such. Many designers of elbow draft-tubes believe that, in designing the bent part, the cross-sectional areas from section to section along the axis should increase in diminishing degree until near the end of the bend there is little or no increase in cross-sectional area from section to section. Then, as the lower leg is encountered, the flare may again be resumed.

EXPERIMENTS WITH PIPE BENDS

Notation.—The symbols used throughout this paper are defined where they first appear. An effort has been made to conform as nearly as practicable with "Symbols for Hydraulics", compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1929. (A.S.A.—*Z*10*b*—1929.)

Theory of Induced Spirals in Pipe Bends.—The bend of the quarter-turn draft-tube is the part in which the greatest complications arise in the function of velocity reduction. In fact, complications are inherent with the flow of water in any channel where the filaments are forced to undergo a general change of direction. If there were stream-line flow of equal velocities at the entrance to a bend, and if friction could be eliminated, no complications of any great import would be encountered. With a whirl component at the entrance to a pipe bend, even without frictional resistance, complications would arise due to gyral action.

No pipe can be made in which frictional resistance to flow will not exist. Therefore, the filaments of flow near the walls of the pipe will be of less velocity than those near the center, and, as the water enters a bend, a spiral flow is induced automatically.

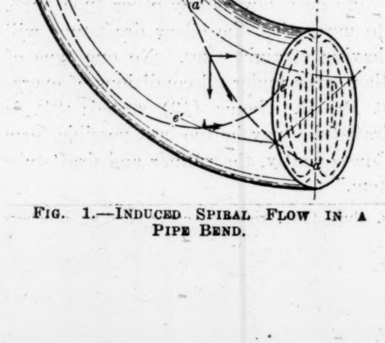

FIG. 1.—INDUCED SPIRAL FLOW IN A PIPE BEND.

As an explanation of the cause of the spiral flow, let a small block of water, b, at a distance, r, from Point O (Fig. 1) have unit length and breadth, and a thickness, dr. Its volume then would be infinitesimally small as represented by the expression: $dQ = dr$; and its mass would be,

$$dm = \frac{w}{g}\, d\,Q = \frac{w}{g}\, dr \text{ ....(1)}$$

in which w = the weight per unit volume; and g = the acceleration of gravity.

From mechanics it is known that the centrifugal force induced by the water moving with a velocity, V, being deflected (20) by a circular bend of radius, r, is:

$$dF = dm\,\frac{V^2}{r} = w\,V^2\,\frac{dr}{r\,g} \text{ ....(2)}$$

The area of the side of the small block is unity, since it is of unit length and breadth, and the intensity of pressure, increased on the left side of the small block caused by the centrifugal force, is:

$$dp = w\,V^2\,\frac{dr}{r\,g} \text{ ....(3)}$$

If the velocities of the filaments between Points a and b are considered equal, and if the inner radius is designated by r_i and the outer radius by r_o, the difference in pressure between these limits integrates into the following:

$$\Delta p = w\,\frac{V^2}{g}\int_{r_i}^{r_o}\frac{dr}{r} = \frac{w\,V^2}{g}\log\left(\frac{r_o}{r_i}\right) \text{ ....(4)}$$

Equation (4) indicates that the difference in pressure caused by the centrifugal force is a function of the square of the velocity. It is similar to the expression for the impulse, or reaction of a jet of water:

$$F = \frac{W\,V}{g} \text{ ....(5)}$$

in which, F = the force, in pounds; V = the velocity of the jet, in feet per second; and W = the flow of water, in pounds per second. The weight, in pounds per second, is then a function of velocity, so that the force, F, is a function of the square of the velocity. Thus, it appears logical that as the bend is encountered the pressure either should be increased at Point e (Fig. 1), or reduced at Point a by some amount, not necessarily exactly equal to that indicated by Equation (4), because the velocities along the traverse between Points a and e are not all of equal magnitude. These velocities will change as the pressures change in the flow around the bend, and perhaps changes will occur even in advance of the bend.

If all the filamental velocities of the water were equal at the entrance to the bend (a condition which could not be obtained easily without a very special apparatus) the pressure at Point d (Fig. 1) would be the same as that at Point *b*; but, due to the lower velocities in the elementary strip, *c-d*, the pressure at Point *d* will be less than that at Point *b*. Therefore, a transfer of water from Point *b* toward Point *d* will tend to take place. Likewise, movement will tend to occur from Point *a* toward Point *b*, and a double spiral is induced. The two principal causes of this condition are: (1) The centrifugal force in the pipe bend; and (2) the existence of friction on the pipe walls so as to give higher velocities near the center of the pipe than near the walls. Under actual conditions the particles of water near Point *e* (Fig. 1), might progress in a path such as *e-e′-e″*, and another particle, such as at Point *a*, might progress in a path such as *a-a′-a″*.

An explanation of the induced spiral probably was offered first by Professor James Thomson (21), in 1876. Recently, tests on the flow of water around bends in pipes were conducted by D. L. Yarnell and the late F. A. Nagler (22), Members, Am. Soc. C. E., at the Iowa Institute of Hydraulic Research. These experiments were undertaken for the purpose of determining the laws governing the changes in pressure and velocity in different parts of the flowing stream, as the moving water undergoes the transition from motion along a straight path to motion around a curve, and then as it undergoes the opposite transition back to final straight-line motion. These experiments are especially valuable because of the numerous Pitot tube measurements of the velocity and pressure at the various sections of the pipe bends. Several different shapes of the pipe bends were used, and tests were made to determine the loss of head due to flow around each bend. The closing statement in the discussion of that paper is of particular interest to the designer of an elbow draft-tube: "Probably the most important finding in the investigation is that it is possible to have such conditions of flow that the loss of head may be very little, or unusually large, in the same bend for identical discharges", depending upon the velocity distribution at the entrance to the bend.

Several of the pipe bends reported in this paper were sent to the Iowa Institute of Hydraulic Research and were tested for flow characteristics. Only part of the results of these tests were described by Messrs. Yarnell and Nagler.

Design of Experimental Pipe Bends.—The general equation of continuity of flow of a fluid is:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho V_x)}{\partial x} + \frac{\partial (\rho V_y)}{\partial y} + \frac{\partial (\rho V_z)}{\partial z} = 0 \ldots\ldots\ldots\ldots (6)$$

in which ρ = density of the fluid; t = element of time; V_x = component of velocity along the X-axis; V_y = component of velocity along the Y-axis; and V_z = component of velocity along the Z-axis.

The density of the water may be regarded as constant, and the equation of continuity becomes:

$$\frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y} + \frac{\partial V_z}{\partial z} = 0 = \text{divergence} \ldots\ldots\ldots\ldots (7)$$

If the motion is irrotational (23) the curl of the velocity vector is zero, and the vector of which V_x, V_y and V_z are components is derivable from a potential.

For irrotational motion, the components of flow in the direction of the axes, X, Y, and Z, are: $V_x = -\frac{\partial \Psi}{\partial x}$; $V_y = -\frac{\partial \Psi}{\partial y}$; and $V_z = -\frac{\partial \Psi}{\partial z}$. The equation of continuity then becomes:

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

which is the Laplace equation.

If this is taken as a special case of two-dimensional flow, say, in the X-Y plane, then,

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The real part, ψ, of any function, $f(x + iy)$, of a complex variable satisfies the equation for the velocity potential, and, at the same time, the imaginary part gives the stream function. Assume that:

$$\Psi + i\Phi = (x + iy)^2 = x^2 - y^2 + 2i(xy) \ldots\ldots\ldots\ldots (10)$$

Therefore,

$$\Psi = x^2 - y^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

and,

$$\Phi = 2xy \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

(b) THEORETICAL FLOW

FIG. 2.—DESIGN OF PIPE BEND NO. 2.

Equations (11) and (12) satisfy the specifications for two-dimensional irrotational flow since the divergence is zero:

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial y^2} = \frac{\partial^2 (x^2 - y^2)}{\partial x^2} + \frac{\partial^2 (x^2 - y^2)}{\partial y^2} = 0 \quad \ldots\ldots\ldots (13)$$

To design a pipe bend from this relation and not to take friction into account, of course, would omit an essential factor in the flow of water in pipes, but it was deemed desirable to try it and observe the results. Accordingly, a bend suitable for a 6-in. pipe was designed, more or less by trial, until that shown in Fig. 2 was obtained. If the co-ordinates, in inches, of the beginning point, *T*, were used as (1, 12) instead of the (1, 18), the angle at Point *D* would become large. To use (0.5, 18) instead of (1, 18) made the width, *A*-*B*, rather large and, at the same time, gave a sharper curve near Point *A*. To avoid an abrupt angle at Point *D*, 1 in. was added to each of the x and y-distances to afford an opportunity to smooth out the hyperbolic curves to meet the parallel filamental flow from the 6-in. pipe at the entrance to the bend. The leg length, *L*, of the pipe thus became 15 in. as shown in Fig. 2.

The distance across the pipe from side-wall to side-wall, measured along the equi-potential lines, is expressed by the equation:

$$D_\Psi = \int \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{0.5} dx \qquad (14)$$

Since, $x^2 - y^2 = C =$ a constant; $2\,x\,dx - 2\,y\,dy = 0$; $\frac{dy}{dx} = \frac{x}{y}$; and, $\left(\frac{dy}{dx}\right)^2 = \frac{x^2}{y^2}$:

$$D_\Psi = \int \left[1 + \left(\frac{x^2}{y^2}\right)^2\right]^{0.5} dx \qquad (15)$$

When $x^2 - y^2 = \Psi = 0$ (which is the special case half-way around the bend), $D_\Psi = 9.87$ in.

The area of the cross-section of the pipe half-way around the bend, Fig. 2, may be expressed mathematically. Assuming, for example, $x\,y = 18 = C$, then $x_1 = \frac{C}{18}$. At the 45° section, $x = y$, so that, $(x_2)^2 = C = 18\,x_1$. Then, $x_2 = 3\,(2)^{0.5}\,(x_1)^{0.5}$; $dx_2 = \left(\frac{3}{2}\right)(2)^{0.5}\,\frac{dx_1}{x_1^{0.5}}$; $dD_\Psi = dx_2\,(2)^{0.5} = 3\,\frac{dx_1}{x_1^{0.5}}$; and, $dA_2 = L\,dD_\Psi = 3\,L\,\frac{dx_1}{x_1^{0.5}}$. Since the radius, r, of the entrance of the pipe is 3 in., the length, L, of the elemental area, dA, is:

$$L = 2\,[9 - (x_1 - 4)^2]^{0.5} \qquad (16)$$

which is the same as the length of the corresponding elemental area for the section half-way around the bend. Then,

$$d\,A_2 = 3\,L\,\frac{dx_1}{x_1^{0.5}} = 6\int_1^7 \left(8 - x_1 - \frac{7}{x_1}\right)^{0.5} dx_1 \qquad (17)$$

Equation (17) is an elliptic integral, which can be evaluated. By plotting the curve to scale and using a planimeter, the area was found to be 47.0 sq in.

The generating angle of a cone having an equivalent increase in area in the same length as this hyperbolic bend between entrance and vertex was computed and found to be 4° 20′, which is well below the usual allowable value of the angle of flare for draft-tubes. This bend hereafter will be referred to as Bend No. 2. Bend No. 1 is a standard 6-in. pipe bend of 90° having a center-line radius of 8 in.

FIG. 3.—DESIGN OF PIPE BENDS.

S. M. Woodward, M. Am. Soc. C. E., has suggested designing a bend with side-walls defined by the cubic equation,

$$y = x - \frac{x^3}{a^2} \qquad \text{(18)}$$

This curve has a slope of 45° at the origin, and is horizontal at its maximum point where $x = a$, and $y = \frac{2a}{3}$. The radius of curvature is infinity at the origin, and is $0.5\,a$ at the maximum point. The part of the curve between the origin and the maximum point was used to make one-half the bend; and then it was turned over to make the other half of the bend, as shown in Fig. 3.

By assuming values of a in Equation (18), the side-walls of the bend were obtained. This bend would always bulge at the vertex. The final dimensions of the bend, as adopted for testing, had a diameter at the vertex of 7.06 in., an entrance diameter of 6 in., and a leg length of 15 in. This was obtained by taking values of a for the inside wall, the axis, and the outside wall, equal to 7.88, 10, and 12.12, in., respectively. By using these values of a the leg length would have become 14.14 in., but this was arbitrarily increased to 15 in., making the additional leg length have parallel side-walls as in a 6-in. cylinder. Hereafter, this pipe bend will be designated as Bend No. 3.

Professor Nagler suggested making a bend having all cross-sections elliptical and of equal area. The axis of the bend was a quadrant with a radius of 15 in. as shown in Fig. 3. The maximum width of section was arbitrarily fixed at 10 in., giving a maximum angle between axis and side-wall of about 10 degrees. It is apparent from Fig. 3 that the side-walls, *B-G* and *B-F*, are not straight lines, but are drawn in to form smooth curves. By assuming the distance, *F-G*, as 10 in., and maintaining an area at the vertex equivalent to that of a 6-in. circle, the ellipse had the dimension, *D-E*, of 3.6 in. Hereafter, this bend will be referred to as Bend No. 4.

Another bend (No. 5) was designed by using the same axis as in the case of Bend No. 3, and applying Equation (18) with $a = 10$ in. The side-walls were designed to constrict the flow at the vertex of the bend, giving an arbitrary minimum diameter of 4 in. The increase in velocity from entrance of bend to the mid-section was assumed to vary as in a straight line in accordance with the theory of a draft-tube, as suggested by F. Prasil (24). The dimensions of this bend are shown in Fig. 3. The differential equation required to represent the reduction in velocity, and the deceleration as a linear function of the distance measured along the axis of the bend is:

$$\tan \alpha = \frac{dr}{dx} = -\frac{r_0}{2x} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

in which r_0 = radius of the pipe; x = distance out from origin to the point where r_0 is measured; and, α = angle between the axis and the side-wall where r_0 is measured. Then, $2\,x\,dr = -\,r_0\,dx$; $2\,x\,dr_0 + r_0\,dx = 0$; $d\,(r^2_0\,x) = 0$; $r^2_0\,x = K$ = constant; $\pi\,r^2_0\,x = K' = A\,x$; and, $\frac{Q\,x}{V} = K'$. Therefore,

$$V = \left(\frac{Q}{K'}\right) x \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

which represents a straight line.

If the velocity is differentiated with respect to time, the result will be deceleration; thus:

$$\frac{dV}{dt} = \left(\frac{Q}{K'}\right)\frac{dx}{dt} = \left(\frac{Q}{K'}\right) V \quad \ldots\ldots\ldots\ldots\ldots\ldots(21)$$

This, again, is a linear equation in x, since $\frac{dx}{dt}$ is velocity. The velocity variation from the entrance to the mid-point of this bend is shown in Fig. 3 for a special case in which the rate of flow is 1.0 cu ft per sec.

TABLE 1.—Summary of Pipe-Bend Dimensions

Bend No.	Vertex area, in square inches	Length of bend on axis, in inches	Generating angle of equivalent conical tube, in degrees	Radius of curvature of axis at vertex of bend, in inches
1..............	28.27	12.6	0	8
2..............	47.00	23.0	4° 20′	12
3..............	38.15	26.4	2° 20′	5
4..............	28.27	23.6	0	15
5..............	12.57	26.4	4° 20′	5

Table 1 shows a summary of the dimensions of Bends Nos. 1 to 5, each of which had an entrance diameter of 6 in., and (except Bend No. 1, in which, $L = 8$), a leg length of 15 in.

Construction of Pipe Bends.—All the pipe bends were constructed of transparent pyralin. After some preliminary experiments it was discovered that this material would become plastic when heated to a temperature of about 275° F, without losing its transparency, and when it was pressed into various shapes and cooled, it again became rigid.

The first stage in the construction of the bends was to make the moulds for pressing the material into the desired shapes. Full-sized drawings were made showing the intersections of planes passed through the bend parallel to, and at distances, in inches, of 1, 2, 3, etc., from the axis. The traces marking the intersection of the planes with the barrel of the pipe formed templates for marking the pieces of 1-in. sugar pine lumber so that they could be cut with a band-saw to the proper shapes. These pieces were then glued together and gouged out with a chisel to obtain the various cross-sections according to the different designs. Allowance was made in the construction of the moulds for the $\frac{1}{8}$-in. thickness of the pyralin between the two parts of each mould.

The material was heated in an electric oven at a temperature of about 275° F, and when the sheets became plastic they were placed between the moulds and pressed into shape. The pieces were put together with cement made by dissolving pyralin in acetone.

If the material was heated too much, it would lose its transparency; if not heated enough, it would wrinkle when pressed into warped surfaces; and, if heated too quickly, the surface became "frosty", and impaired the transparency. The "frosty" condition was overcome by rubbing the material with water sand-paper and polishing it with pumice.

Laboratory Experiments with Pipe Bends.—Fig. 4 shows the general arrangement of the apparatus during a test. The water, admitted at Point *K*, flowed through a conical expanding tube, and was deflected by a flat plate, into Tank *A*. A conical bottom, *C*, and guide-vanes in the bottom of the head-water tank directed the water, with or without a whirl component as desired, into a vertical pipe, *D*, 6 in. in diameter and 24 in. long, above the bend. The bend to be tested is indicated by *F*. After leaving the bend, the water flowed through a straight section of 6-in. pipe, 32 in. long, to a second tank, *B*. This tank was open at the top and fitted with a discharge valve at Point *H*.

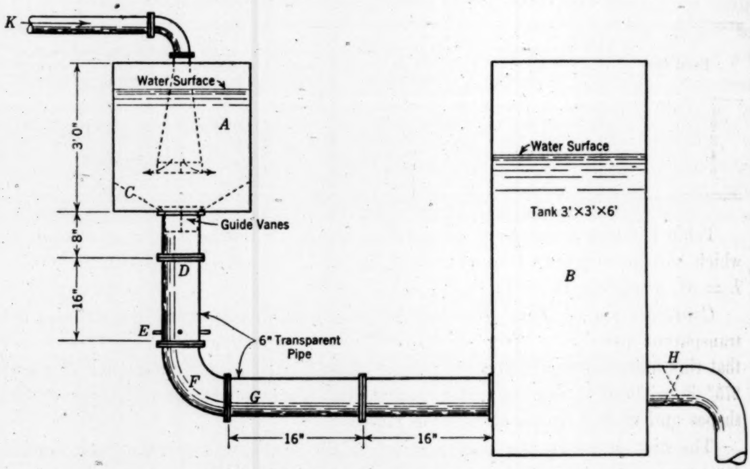

FIG. 4.—DESIGN OF LABORATORY APPARATUS.

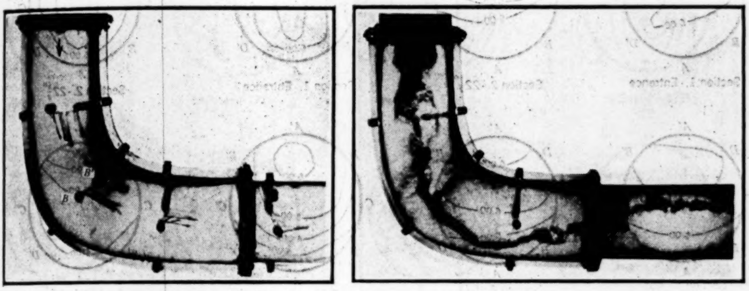
The velocities of the water filaments were measured with a Pitot tube which was calibrated at the State University of Iowa, the Colorado Agricultural College, and at the Oregon State College. Its coefficient was found to be 0.86.

The rate of flow was determined by volumetric measurement. The water flowing from the test apparatus was collected in a concrete tank, and by use of a stop-watch and point-gage, readings were taken to determine the time required to raise the water surface to a given level in the tank so that the rate of flow could be established.

The bends were tested with two types of flow: (1) Direct flow without whirl component; and (2) helical flow, or that with a whirl component at the entrance to the bend. It has been stated that when the water approaches the bend with approximately uniform filamental velocities, there will be an induced double spiral as shown in Fig. 1. That this double spiral actually developed to a marked degree is indicated by Fig. 5(*a*), which is a view of the direct flow in Bend No. 3. At the vertex of the bend is shown a string stretched from the Pitot tube connections marked *B-B'*, and attached to this string are several short pieces of yarn. The yarns show that the filaments of flow near the side-walls of the pipe, as at *B* and *B'*, have velocity components toward the inside of the bend, whereas the filaments of flow near the center of the pipe have velocity components toward the outside wall of the bend. A double spiral flow has been induced, as shown in Fig. 1.



(*a*) Direct Flow. (*b*) Helical Flow.

Fig. 5.—Direct and Helical Flow in Bend No. 3.

It is possible for a single spiral to exist in a pipe bend, with the water rotating in one direction or the other, depending on the flow at the entrance to the bend. This was shown in a series of experiments conducted by Messrs. Yarnell and Nagler (22) in 1934, in which the water at one side of the entrance to the bend had higher filamental velocities than on the other side. On the side where the axial velocities were small the water would move toward the inside, and on the side where the axial velocities were large the water would move toward the outside, of the bend, causing a single spiral instead of a double spiral.

Fig. 6 shows the velocity contours at different sections of Bends Nos. 1, 2, 3, and 4. In these diagrams the points marked *A* are at the outside of the bend, and the points marked *A'* are at the inside of the bend. In all cases the view is looking down stream. From these diagrams it is evident that, as the water approached the bend, the filaments of flow along the inside of the bend accelerated until they reached a maximum velocity about half-way around the bend. From that point the thread of maximum velocity moved to the outside of the bend.

Attention should be called to the unsymmetrical velocity contours in Bends Nos. 2 and 4. This was caused by having the cone in the head-water tank, *A* (Fig. 4), slightly off center. When this cone was centered the velocity contours were symmetrical about the center of the pipe, as shown for Bends Nos. 1 and 3 (see Fig. 6). It should be noted that any minor disturbance up stream from the bend was found to be reflected in the velocity distributions throughout the bend.

Curves were drawn for the combined velocity head and pressure head for all bends, as shown in Fig. 7. In the data the pressure has been recorded as p, for brevity, which was the indicated pressure head as given by the pressure

FIG. 7.—COMBINED VELOCITY-HEAD AND PRESSURE-HEAD CONTOURS AT DIFFERENT SECTIONS OF EXPERIMENTAL BENDS.

orifice of the Pitot tube. To obtain the corrected pressure head the equation for the Pitot tube was used:

$$V = 0.86 \ (2 g h)^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

From Equation (22) h was computed for all the readings, added to $\frac{V^2}{2g}$, and plotted as shown in Fig. 7.

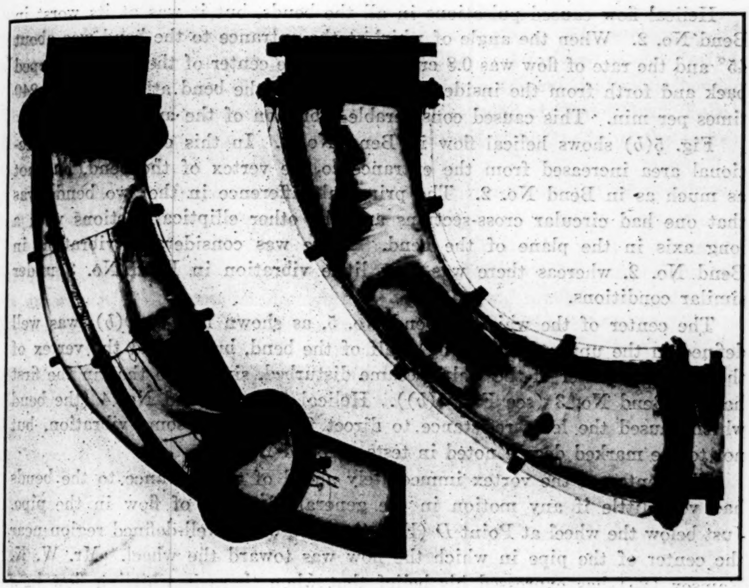
Tests were made to ascertain which of the bends induced the least loss of head for a given rate of flow. A bend was placed in the apparatus as shown at F in Fig. 4, and the water was admitted at a given rate so that the elevations of the water surfaces in Tanks A and B could be determined. This was repeated for all the bends, keeping the rate of flow constant. Bend No. 4 offered the least resistance to flow. As a check against this result, the bends were tested for head loss due to friction, by Messrs. Yarnell and Nagler (22) who found that, in a straight 6-in. pipe, the loss was 0.0302 $\frac{V^2}{2g}$ per ft of pipe. The loss of head in the several bends, expressed in terms of the velocity head, and exclusive of frictional resistance, was as follows:

Bend No.	Loss of head in 90° bend (exclusive of friction)
1	$0.15 \ \frac{V^2}{2g}$
2	$0.15 \ \frac{V^2}{2g}$
3	$0.17 \ \frac{V^2}{2g}$
4	$0.13 \ \frac{V^2}{2g}$

This tabulation shows that Bend No. 4 offers less resistance to flow than any of the others, the advantage over Bend No. 3 being more than 30 per cent. Its advantage over the standard short-radius bend was more than 15 per cent. By an inspection of Figs. 5(a) and 8(a) it will be apparent that the induced spirals were more pronounced in Bend No. 3 than in Bend No. 4. Bend No. 4 has an additional advantage over the other bends when applied to elbow draft-tubes because it is flattened properly to avoid excessive excavation. This was a fortunate finding in the light of draft-tube construction, because of the desirability of widening the tube laterally to reduce excavation costs.

Helical flow, or that with a whirl component at the entrance to the bend, was produced by placing a stationary wheel in the apparatus at Point D (see Fig. 4). Only one type of whirl was used, where the rotation appeared to be counter-clockwise, facing down stream.

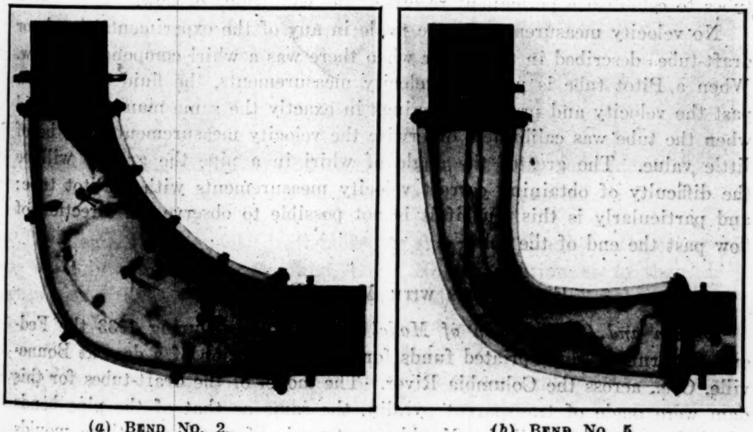
Bend No. 2 is shown in Fig. 9(a) with whirling component of flow at the entrance. The dark areas were made by admitting air in the stream of



(a) DIRECT FLOW. (b) HELICAL FLOW

FIG. 8.—DIRECT AND HELICAL FLOW IN BEND NO. 4.

inflowing water. The air bubbles moved into the region of least pressure, near the center of the whirl, and when a light was placed behind the pipe the air bubbles intercepted the light.



(a) BEND NO. 2. (b) BEND NO. 5.

FIG. 9.—EXAMPLES OF HELICAL FLOW.

Helical flow caused pulsations in all the bends, but it was at its worst in Bend No. 2. When the angle of whirl at the entrance to the bend was about 45° and the rate of flow was 0.8 cu ft per sec, the center of the vertex whipped back and forth from the inside to the outside of the bend at the rate of 240 times per min. This caused considerable vibration of the apparatus.

Fig. 5(*b*) shows helical flow in Bend No. 3. In this case the cross-sectional area increased from the entrance to the vertex of the bend, but not as much as in Bend No. 2. The principal difference in the two bends was that one had circular cross-sections and the other elliptical sections with a long axis in the plane of the bend. There was considerable vibration in Bend No. 2, whereas there was very little vibration in Bend No. 3 under similar conditions.

The center of the whirl in Bend No. 5, as shown in Fig. 9(*b*), was well defined in the upper (converging) half of the bend, but beyond the vertex of the bend the center of the whirl became disturbed, similar to that in the first half of Bend No. 3 (see Fig. 5(*b*)). Helical flow in Bend No. 4 (the bend which caused the least resistance to direct flow) caused some vibration, but not to the marked degree noted in tests of Bend No. 2.

The center of the vortex immediately ahead of the entrance to the bends had very little if any motion in the general direction of flow in the pipe. Just below the wheel at Point *D* (Fig. 4), there was a well-defined region near the center of the pipe in which the flow was toward the wheel. Mr. W. K. Ramsey (25) has expressed his belief that when there is whirling flow in a draft-tube, whether of straight or curved axis, there is a backward movement of water in the center of the whirl extending from the exit of the tube to the turbine runner. In none of the experimental bends or model draft-tubes described in this paper did the region of backward movement of water extend half-way around the bend, and in most cases it did not reach as far as the bend. Motion pictures were made of the flow through all the bends and draft-tubes to establish a permanent record of the conditions of flow.

No velocity measurements were made in any of the experimental bends or draft-tubes described in this paper when there was a whirl component of flow. When a Pitot tube is used for velocity measurements, the fluid should flow past the velocity and pressure openings in exactly the same manner as it did when the tube was calibrated, otherwise the velocity measurements may be of little value. The greater the angle of whirl in a pipe the greater will be the difficulty of obtaining correct velocity measurements with a Pitot tube; and particularly is this true if it is not possible to observe the direction of flow past the end of the tube.

EXPERIMENTS WITH MODEL DRAFT-TUBES

Design and Construction of Model Draft-Tubes.—During 1933 the Federal Government appropriated funds for the construction of a dam at Bonneville, Ore., across the Columbia River. The model of the draft-tubes for this dam were made of transparent pyralin, the same as that of the pipe bends which have been described. Moulds were made of wood, and these moulds were used to press the sheets of transparent material into the desired shapes. Some trouble was encountered in pressing the flat sheets into such warped shapes, but for the most part a fairly workmanlike and finished model draft-tube was obtained. Fig. 10 shows the moulds for a typical draft-tube bend. The mould on the left was for the lower half of the bend of Model Draft-Tube No. 1, and that on the right was for the inner half of the bend of the same tube.

Pyralin is much superior to glass as a transparent material of which to build model draft-tubes because of its durability and ease of fabrication. Prasil (26) used glass in the construction of a draft-tube with a straight center line, but no mention was made of the use of Pitot tube connections in his experiments. Piezometer connections can be made much more easily of pyralin than of glass, and with less trouble due to breaking.

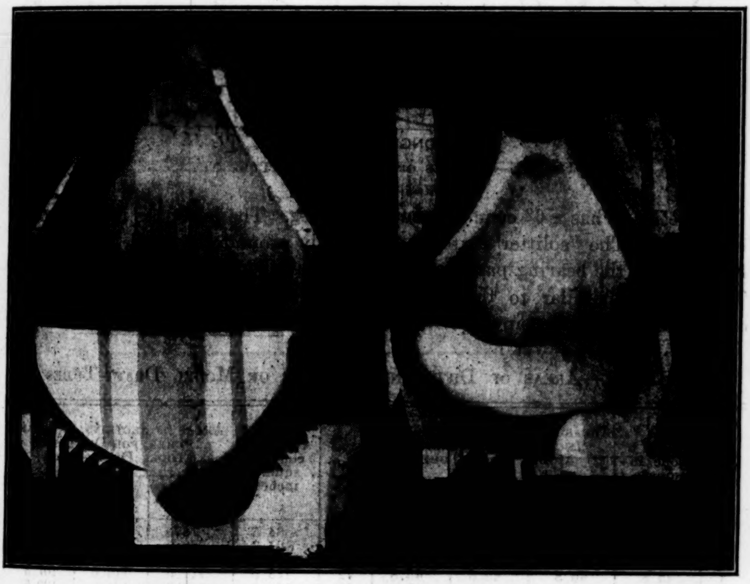


FIG. 10.—MOULDS FOR BEND OF MODEL DRAFT-TUBE NO. 1.

The design of the model draft-tubes for the U. S. Engineer Department was made in the office at Portland, Ore. No information as to their design was available to the writer other than the detail drawings, such as shown in Fig. 11, Draft-Tube No. 1, and the cross-sectional areas at different points along the axis of the tubes, as shown in Table 2. The cross-sections of Tube No. 1 are not circular at any point along its axis except at the entrance. The tube expands at the same rate as a cone having a 6° generating angle. There is no "splitter", and the bearing partition does not enter the bend. The distinctive feature of this bend is the manner in which the walls are "dished" down on the inside of the bend and lower leg.

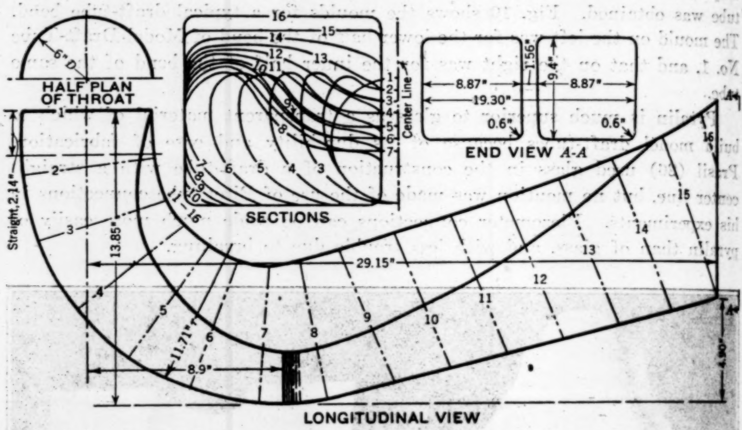

FIG. 11.—DETAILS OF MODEL DRAFT-TUBE NO. 1.

Tube No. 2 has a 6° cone for the vertical leg. The lower leg is rectangular in section. The "splitter" extends completely around the bend, as shown in Fig. 12, and the bearing partition terminates at about the middle of the bend. This tube is similar to the draft-tubes built at Ryburg-Schwörstadt (27) on the Rhine, in Germany.

TABLE 2.—AREAS OF DIFFERENT SECTIONS OF MODEL DRAFT-TUBES

Section No.	Area of 6° cone, in square inches	Areas of Sections, in Square Inches, for Different Model Draft-Tubes			Section No.	Area of 6° cone, in square inches	Areas of Sections, in Square Inches, for Different Model Draft-Tubes		
		Tube No. 1	Tube No. 2	Tube No. 3			Tube No. 1	Tube No. 2	Tube No. 3
1	28.3	28.3	28.3	28.3	9	84.5	76.0	83.7	68.5
2	33.6	33.6	33.6	33.6	10	91.7	88.7	96.5	81.0
3	39.4	39.0	39.4	39.4	11	103.0	100.3	104.5	94.5
4	45.8	46.8	45.6	45.8	12	113.0	111.0	114.0	107.5
5	52.6	53.5	54.3	47.0	13	124.0	122.3	124.0	120.5
6	60.0	61.5	60.0	45.5	14	135.0	132.8	135.5	134.0
7	67.7	60.0	66.4	45.5	15	146.0	143.0	148.5	146.5
8	75.7	65.0	75.0	55.5	16	159.0	153.0	.....	.....

Tube No. 3 is dished on the inside of the bend, but to a less degree than Tube No. 1. The vertical leg widens in a direction normal to the plane of the bend, and there is no "splitter." The areas of the sections at different points along the axis of the tube are about the same as that for a 6° cone as given in Table 2. The bearing partition extends almost completely around the bend, as shown in Fig. 13.

Design of Model Draft-Tube No. 4.—This tube was designed for the same setting as the model draft-tubes for the U. S. Engineer Department. The given data were: (1) Elevation of entrance of draft-tube; (2) entrance diameter; (3) elevation of top edge of outlet; (4) maximum width; and, (5) normal discharge. The vertical leg of the tube was made as long as it could be conveniently, so that the velocity would be reduced before the water entered the bent part of the tube. It was trumpet-shaped, as suggested by Prasil (24). This type of vertical leg appeared to have certain advantages since the deceleration at the entrance of the tube was small and there seemed

to be less likelihood of inducing cavitation. The length of the vertical leg used was the same as that of Tube No. 2—7.23 in.—and the entrance was 6 in. in diameter.

The angle of flare of 7° was selected after considering earlier tests by the writer and by Hofmann (8). Draft-Tube No. 2, which showed a very high efficiency, had an angle of flare of 6 degrees. Hofmann reported that an angle of flare of 8.5° could be used to advantage, and common practice in draft-tube design has shown that a flare somewhat greater than 6° could be used.

For purposes of design, the rate of flow was taken as 1.0 cu ft per sec. The mean velocity in the 6-in. entrance to the tube was 5.08 ft per sec. Then, at Section 7.23, the radius of the tube became: $r_0 = 3.00 + 7.23 \tan 7°$ $= 3.89$ in.; and, $V = \frac{Q}{A} = \frac{144}{\pi\,(3.89)^2} = 3.03$ ft per sec. These values are to be substituted in Equation (20) which was derived by use of the theory suggested by Prasil (24). At the entrance to the tube (see Fig. 14), x was found to be 17.94 in. and, consequently, the rate of deceleration at that point becomes $\delta_0 = \left(\frac{Q}{K'}\right)^2 x_0$ $= [(5.08)\ (12) \div 17.94]^2\ (17.94 \div 12) = 17.25$ ft per sec²; and at Section 7.23, $\delta_{7.23} = (3.4)^2 \times \frac{(17.94 - 7.23)}{12} = 10.3$ ft per sec.² The reduction of velocity per inch of distance along the axis is, $\frac{(5.08 - 3.03)}{7.23} = 0.2835$ ft per sec per ft; the velocity at Section 10 is, $V_{10} = 5.08 - 10\,(0.2835) = 2.25$ ft per sec; and, $\delta_{10} = 17.25 - \frac{10}{7.23}\,(17.25 - 10.3) = 7.63$ ft per sec.²

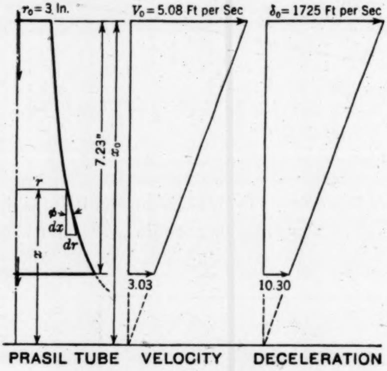

FIG. 14.—STRAIGHT-LINE VELOCITY AND DECELERATION CURVES IN PRASIL DRAFT-TUBE.

From Section 10 the increase in area of the tube is the same as that for a 7° cone. It should be noted that where the change occurs from a Prasil section to a conical section, there is an abrupt change in the deceleration, as shown in Fig. 15. The deceleration in a cone is given by the equation:

$$\delta_x = \frac{2 \tan \phi\,(V_x)^{2.5}}{r_0\ V_0^{0.5}} \qquad (23)$$

in which, r_0 = radius of cone at entrance of tube; V_0 = entrance velocity of water; and, V_x = velocity of water at any other section where deceleration is desired. The radius of a circle having an area of 0.448 sq ft at Section 10, is 4.53 in., which, substituted in Equation (23), yields, $\delta_{10} = \dfrac{2\,(\tan 7^\circ)\,(2.25)^2}{\dfrac{4.53}{12}}$ $= 3.3$ ft per sec^2. Thus, the deceleration drops suddenly from 7.6 ft per sec.^{2} to 3.3 ft per sec.^{2}, as shown in Fig. 15. The deceleration at the entrance of the Prasil tube was computed to be 12.16 ft per sec.^{2}, as compared to 15.3 ft per sec.^{2} at the entrance of a 6° cone.

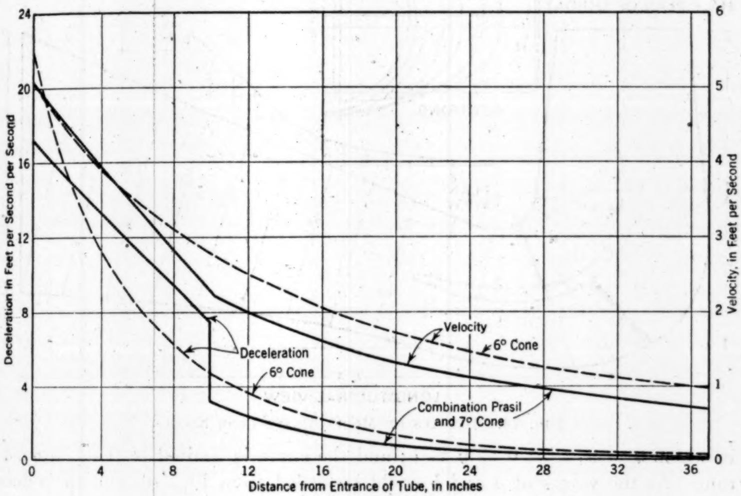

Fig. 15.—Velocity and Deceleration in Model Draft-Tube No. 4

The horizontal leg of the draft-tube, as designed, was rectangular in section. The upper wall was a plane surface, the sides were parallel, and the floor slope was varied in the direction of flow to provide for the increase in area necessary to obtain the flare equivalent to a 7° cone. Fig. 16 shows the details of the model draft-tube.

At the upper end of the bent part the cross-sections were circular and at the lower end they were rectangular. The side curves were drawn in to obtain a smooth curve as shown in the plan view. The outside curves were drawn as smooth lines without any mathematical relation from which to establish them.

The cross-sections of the bend in the draft-tube were patterned after the energy and velocity contours obtained for the test on Bend No. 4 and shown in Sections 4, Figs. 6 and 7. The general plan of the design of the cross-sections of the bend was as follows: At the beginning of the bend, use a circular cross-section; at 22½°, use an elliptical section; at 45°, use an ellipse of greater eccentricity for the inside than for the outside part of the section; and, at the end of the bend, use a rectangular section.

An equation suitable for obtaining such curves as could be used for the sections between the vertex and the end of the bend where the transition must be made from an ellipse to a rectangle, has the general form:

$$\left(\frac{x}{a}\right)^n + \left(\frac{y}{b}\right)^n = 1 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

FIG. 16.—DETAILS OF MODEL DRAFT-TUBE NO. 4.

in which $0 \leq x \leq a$; $0 \leq y \leq b$; and the curve is limited to the first quadrant. As the values of a and b could be scaled from Fig. 16, and the values of the exponent, n, could be varied to obtain the approximate total cross-section that would give the required area, an exact definition of the cross-sections could be given. However, this refinement was not necessary, and no further mathematical analyses of the sections of the bends were made.

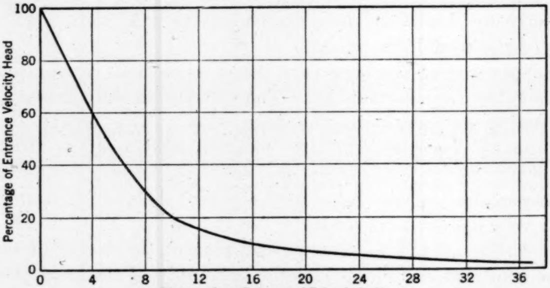

FIG. 17.—PERCENTAGE OF VELOCITY HEAD REMAINING AT VARIOUS SECTIONS OF MODEL DRAFT-TUBE NO. 4.

Fig. 17 shows the percentage of the entrance velocity head that remains in the water at different sections of Model Draft-Tube No. 4, the flow at the entrance being 1.0 cu ft per sec. From this curve it is evident that the major portion of the velocity head should be reclaimed in the vertical leg of the tube.

Laboratory Tests on Model Draft-Tubes.—The tests of the model draft-tubes were made with the same apparatus that was used in testing the experimental pipe bends (see Fig. 4). The only change in this apparatus was to fasten the lower, or outlet, end of the draft-tube to Tank *B*. The throat of the draft-tube was fastened to the same flange to which the entrance of the pipe bend was fastened, as at Point *E*.

The water that flowed through the draft-tube was measured by volume to establish the rate of flow, which was regulated by the valves in the inlet pipe, *K*, and in the outlet pipe, *H*.

Each draft-tube was tested first with a direct flow of the entering water. The pressure at the throat of the tube was obtained through four piezometer connections spaced at equal intervals around it, and the pressure at the exit of the tube was obtained from the elevation of the water surface in the tank, *B*. Pitot tube measurements of velocities in the lower leg of two of the draft-tubes were recorded for several different rates of flow, both with and without the "splitter" in place.

To obtain whirling flow in a draft-tube, a special set of curved vanes was used above the entrance to the tube replacing the guide-vanes shown in Fig. 4. Air was admitted with the water to assist in observing and photographing the position of the center of the whirl. Motion pictures were taken of all the different conditions of flow.

The efficiency of a draft-tube as a regainer of static pressure has been defined in various ways. To the writer it seems logical to define it as the ratio of the head actually recovered to the head available for recovery, or,

$$e = \frac{\text{Regain}}{\text{Throat velocity head}} = \frac{\dfrac{p_2}{w} - \dfrac{p_0}{w}}{\dfrac{V_0^2}{2g}} \quad \ldots\ldots\ldots\ldots\ldots (25)$$

in which p_2 = the pressure head at the exit of the tube; p_0 = the pressure head at the throat of the tube; and V_0 = the velocity at the throat of the tube. The Power Test Code of the American Society of Mechanical Engineers (28) recommends deducting the velocity head at the exit of the tube in computing efficiency. Luksch (6) stated that if the discharge velocity is deducted in computing the efficiency of a draft-tube the result would be indeterminate if applied to a straight cylinder, and he concluded "that it is not justified to account for the discharge energy out of the draft tube, $\frac{V^2}{2g}$, as acting in the sense of an improvement of the efficiency of a draft tube."

No method was devised by the writer for obtaining the efficiency of draft-tubes for conditions of whirling flow. When the water had a whirling motion at the entrance to the tube, the pressure as indicated by the piezometers at the walls of the pipe gave no indication of the mean pressure at that point. Under the conditions of testing as shown in Fig. 4, the pressure at the center of the entrance pipe of the draft-tube was below atmospheric, whereas the pressure near the walls of the entrance pipe was decidedly above atmospheric.

Table 3 shows the efficiencies of the several draft-tubes under conditions of direct flow. Draft-Tube No. 2 showed the highest efficiency (about 65%), indicating that it actually converted into pressure head about 65% of the velocity head at the throat of the tube.

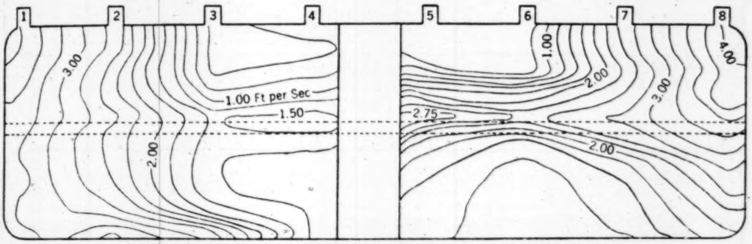
When the horizontal "splitter" in Draft-Tube No. 2 was removed, the tests, summarized in Table 3, showed that the efficiency was lowered about 2 per cent. Of course, some of the cross-sectional areas of the bend were increased about 10% or 15%, but the writer does not believe this could account entirely for the reduced efficiency.

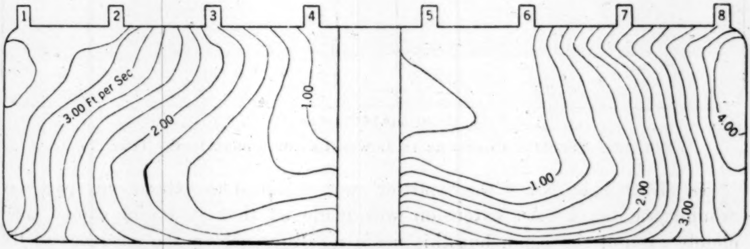
Draft-Tubes Nos. 1 and 3 had an efficiency of about 47 per cent. These two tubes had the central portion of the top surface of the entrance to the lower leg "dished down" very much in the same manner as shown in drawings of a draft-tube developed by G. A. Jessop, Assoc. M. Am. Soc. C. E. (29). Although the lowering of the roof part of the entrance of the lower leg might have been expected to eliminate the dead-water space common in some elbow draft-tubes and thus show good efficiency as a regainer the results were not very good.

There appeared to be no marked difference in the efficiency of the tubes for the different rates of flow. The efficiency was about the same for the lowest rate of flow as for the highest rate; therefore, the fluctuations in efficiency as shown in Table 3 were attributed to experimental error. In tests on draft-tubes having throat diameters of 3 in., Gibson and Labrow (30) concluded that the efficiency was sensibly independent of the velocity for velocities exceeding about 5 ft per sec. In an investigation of the transformation of water velocity into pressure with diffusers having a throat diameter of 75 mm, K. Andres (31) found that the efficiency exhibited by any tube was independent of the velocity over a range of velocities between 30 and 130 ft per sec.

The Pitot tube measurements of the velocities near the entrance (Section 10) of the lower leg of Draft-Tube No. 2, both with and without the "splitter", and facing in the direction of flow, are shown in Fig. 18. From these curves, it is evident that the "splitter" had a material effect on the filamental velocities, but did not eliminate entirely the region of lessened velocities near the inner part of the exit of the bend. From the curves it appears that the velocities were higher near the right side of the tube, looking down stream, than on the left side. This was found to have been caused by the flaring tube in Tank *A* (Fig. 4), being about $\frac{1}{2}$ in. off center. When the flaring tube was adjusted to the center of Tank *A*, its two sides showed approximately symmetrical conditions of flow.



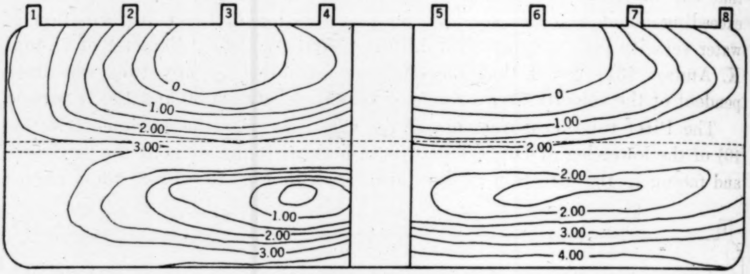
(*a*) With Horizontal Splitter and Vertical Bearing Partition; Avg Q = 1.204 Cu Ft per Sec



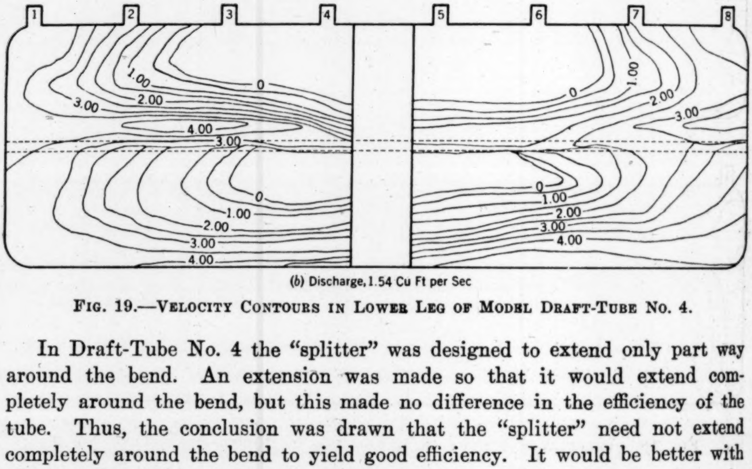
(*b*) With Vertical Bearing Partition; Avg Q = 1.193 Cu Ft per Sec

FIG. 18.—VELOCITY CONTOURS IN LOWER LEG OF MODEL DRAFT-TUBE NO. 2.

Fig. 19 shows velocity contours at a section (Section 20) near the exit of the bend of Draft-Tube No. 4, facing in the direction of flow. It is evident that there was considerable dead water near the inside of the bend, a condition that did not exist in Tube No. 2. The reason for the occurrence of the dead water was attributed to too great a distance between the top and bottom walls of the exit of the bend, a measurement hereafter designated as the Δ-distance of the tube.



(a) Discharge, 1.23 Cu Ft per Sec



(b) Discharge, 1.54 Cu Ft per Sec

FIG. 19.—VELOCITY CONTOURS IN LOWER LEG OF MODEL DRAFT-TUBE NO. 4.

In Draft-Tube No. 4 the "splitter" was designed to extend only part way around the bend. An extension was made so that it would extend completely around the bend, but this made no difference in the efficiency of the tube. Thus, the conclusion was drawn that the "splitter" need not extend completely around the bend to yield good efficiency. It would be better with whirling flow if the "splitter" were limited to a position about as shown in Fig. 16.

With whirling flow there was considerable turbulence throughout the length of all the draft-tubes. This was at its worst with those tubes having the "splitter", such as Tube No. 2, if the "splitter" extended completely around the bend. An attempt was made to correct the turbulence in Tube No. 2 by placing a "twisted fin" on the upper end of the "splitter." The results of this experiment are shown in Table 4.

The loss of head in flow through the tube was somewhat reduced by the "fin", but the difference was not great. It is known that the whirl component of the filamental velocities in draft-tubes may be clockwise at one time and counter-clockwise at another, depending upon the changes in head and gate-opening It is possible that the whirl may be clockwise near the walls of the draft-tube and counter-clockwise near the center of the tube. It is evident, therefore, that the use of any such deflector as described herein for correction of whirl in a draft-tube is not practicable.

RECOMMENDATIONS FOR THE DESIGN OF ELBOW DRAFT-TUBES

The Vertical Leg.—An elbow draft-tube should have a trumpet-shaped vertical leg as long as the suction head and the construction costs will permit. A long vertical leg seems to be justified by the fact that the bent part of an elbow draft-tube induces spiral flow and, consequently, friction and eddy losses which vary approximately as the square of the velocity of the flowing water. If there is a vertical leg in a draft-tube, the induced spiral velocities in the bend and the resultant hydraulic losses should be smaller than in an elbow draft-tube which has no vertical leg.

As indicated in Fig. 17, there is a greater conversion of kinetic energy to potential energy per foot of draft-tube where the mean velocity is high than where it is low. This is due to the fact that the velocity head varies as the square of the velocity. In the case of Model Draft-Tube No. 4, it would be theoretically possible, under ideal conditions, to obtain an efficiency of more than 80% with the tube cut off at Section 10. Of course, it would be impossible to obtain ideal conditions where there would be no friction and eddy losses, but there can be a closer approach to ideal conditions in a straight pipe than in a curved pipe. Friction on pipe walls cannot be eliminated, and centrifugal force is inherent to change in the direction of flow. These two in combination induce spiral flow as shown in Fig. 5(*a*). The induced spirals cause hydraulic losses that would not occur in a straight pipe.

There is a possibility that the induced spirals due to the bend in an elbow draft-tube may approximately offset the undesirable whirl components of flow from a turbine runner. It is very doubtful, however, whether a designer, either by chance or by careful planning, could discover the combination of conditions needed for this delicate balance. Further research along this line may be expected in the future, since rational and experimental evidences have been submitted (32) (33) (34) by many able engineers in support of their conclusions that the form of draft-tube affects the performance of the runner.

The trumpet shape of the vertical leg, such as that suggested by Prasil (24) seems to be preferable to the straight circular cone. The experiments of Hofmann (8) Gibson and Labrow (30) and Andres (31) indicate that the trumpet-shaped tube has as great an efficiency as a straight cone, or greater. The cone-shaped tube has a further disadvantage that at the entrance to the tube the deceleration is comparatively high and is changing rapidly. This occurs in a region where cavitation troubles may arise. Research at the Massachusetts Institute of Technology (35) shows that cavitation is a mechanical phenomenon in which there is a rapid formation and collapse of small cavities in the flowing water. It appears that the rapidly changing decelerating force at the entrance of a conical tube would make a turbine runner more susceptible to cavitation than the lesser decelerating forces in the trumpet-shaped draft-tubes. It seems, therefore, that the vertical leg of a draft-tube should be trumpet shaped.

The Bend.—In the test of the experimental pipe bends it was shown that Bend No. 4, which was widened in the direction normal to the plane of the bend, offered the least resistance to flow. This was a fortunate finding, because of the ease with which this type of bend can be adapted to an elbow draft-tube.

In the report of the Bureau of Standards (16) on the investigation of literature on draft-tubes, the following statement was made:

> "* * *, some conditions for improving the efficiency of elbow type draft tubes will be stated, which probably are correct, since apparently they are all met with in practically all the elbow tubes of the better design. First, the curvature of the inside wall should be sharp, reducing the length of the curve. Secondly, the depth of the tube at the section where the water is deviated should be small. Third, where the inside wall has considerable curvature, the areas of the sections from point to point should be nearly constant."

It is interesting to note that Bend No. 4 essentially fulfills all these conditions, since the radius of curvature of the inside wall is smaller than that of the outside wall, all the cross-sectional areas are alike, and the pipe is flattened in the plane of the bend.

This flattening, arranged so that the depth of the draft-tube at the exit of the bend is small, seems to be of considerable importance. Draft-Tube No. 2 (Fig. 12) has less depth at the exit of the bend than Draft-Tube No. 4 (Fig. 16). Otherwise, the shapes are quite similar Draft-Tube No. 2 had no dead-water space in the lower leg (Fig. 18), whereas Tube No. 4 had considerable dead-water (Fig. 19), with a resultant lowered efficiency.

Luksch (6) has shown that with direct flow in a trumpet-shaped draft-tube, the maximum efficiency occurred when the impact plate was placed so that $\frac{\Delta}{D_0} = 0.27$, in which Δ = the distance between the impact plate and the bottom of the draft-tube; and D_0 = the throat diameter of the draft-tube.

With values of $\frac{\Delta}{D_0}$ greater than 0.27, the water would jump free from the inner face of the tube and permit the formation of a dead-water zone. This same phenomenon probably occurs in an elbow draft-tube, because the bottom part of the bend acts in a manner similar to an impact plate.

It was stated that the radius of curvature of the inside wall of the bend should be smaller than that of the outside wall. Just what relation these radii should have to the throat diameter of the tube is not known, but some notion may be had from the experiments of Hofmann (8) who showed that if an impact plate is used below a conical draft-tube with rounded bottom edges, the most favorable ratio for rounding is, $\frac{r}{D_0} = 0.85$, in which D_0 = the throat diameter of the tube; and r = the radius of the rounded bottom edges of the draft-tube. He showed, furthermore, that $\frac{r}{D_0}$ may vary between 0.67 and 1.00 without much change in efficiency of the tube. This indicates that the elbow draft-tube may have a wide range of values of the radius of curvature for the inner walls of the bend without losing materially in efficiency.

The shape which should be given the curve shown as the plan view, in Fig. 16, seems to be of no great importance, except that preferably, it should be a smooth curve. In all the model draft-tubes tested by the writer the water had comparatively high velocities of flow along the sides of the tubes, as shown in Figs. 18 and 19.

The cross-section at the entrance of the bend should be circular, and, at the exit, it could well approach that of a rectangle. The intermediate sections should be flatter on the inside of the bend than on the outside.

A "splitter" should be used in the bend of an elbow draft-tube because of its tendency to assist in getting the water around the bend in an orderly manner. Tests on Draft-Tube No. 2 gave about 2% higher efficiency with the "splitter" than without it. In the Lilla Edet (17) tests, where the draft-tube had practically no vertical leg, the "splitter" increased the efficiency slightly.

It is undesirable to extend the "splitter" completely around the bend. Tests with Draft-Tube No. 4 were made first with the "splitter" beginning at about one-third the way around the bend (Fig. 16) and then extended so that it began at the very entrance to the bend. No noticeable change in the efficiency was observed. Caflisch (36) tested a turbine of the Francis type for which he showed that the "splitter" reduced the efficiency when extended into the vertical leg of the draft-tube. This reduction was to be expected, as the turbine caused a whirl component of flow at the part gate-opening. At the larger gate-openings the "splitter" seemed to have little effect on the efficiency. Had it been extended only part way around the bend, such as at the Kembs Power Plant (37), on the Rhine, there probably would have been less turbulence at part-gate operation.

Professor Spannhake (38) has mentioned the desirability of whirl in the draft-tube in the positive sense of the rotation of the runner, this whirl allowing the runner blades to be designed for lower relative velocities and, in consequence, for reduced possibility of cavitation. If this should be the practice, then the extension of the "splitter" into the vertical leg is undesirable. However, it does seem desirable to have both the "splitter" and the vertical bearing partition, commonly built in the lower leg of the tube, extend some distance into the bend.

The Lower Leg.—The length, and particularly the width, of the lower leg of an elbow draft-tube greatly influence the design of the power house. Generally, the width of the draft-tube controls the spacing of the turbines, and the type and size of the plant determine whether or not a bearing partition shall be used in the lower leg of the draft-tube as a means of giving stability to the power-house structure.

The proportions that should be given the lower leg of elbow draft-tubes have been the subject of an investigation (39) for the Wheeler Dam, in the Tennessee Valley. Several tubes were tested with the result that the best efficiency in each tube was obtained when the length of the lower leg was the longest tested. In Plate A-6 of the report (15) of the National Electric Light Association on draft-tubes, are given the results of tests on changing the length of the lower leg of an elbow draft-tube by the Newport News Shipbuilding and Drydock Company. Leg lengths of 2.50, 3.00, and 3.71 times the throat diameter of the tube were used, and the efficiency of the tube was increased with each increase in leg length. This does not mean that the length could be increased indefinitely with a continued increase in efficiency. Hofmann's tests (8) on conical tubes led him to conclude that at first an increase of the length of a draft-tube will cause an improvement in efficiency and, finally, that the wall friction becomes too great and causes a decrease in efficiency. Further experiments are required to determine what the optimum length of the lower leg of an elbow draft-tube should be.

SUMMARY AND CONCLUSIONS

Experiments with Pipe Bends.—

(1) The loss of head due to the flow of water through a standard 6-in. pipe bend of 8-in. axial radius was 0.15 $\frac{V^2}{2g}$ as compared to values of 0.13 $\frac{V^2}{2g}$ to 0.17 $\frac{V^2}{2g}$ for the other pipe bends tested. The specimen that offered the least resistance to the flow of water was flattened in the plane of the bend. Its superior performance probably was due to the fact that fewer induced spirals occurred in this form than in the other bends.

(2) The specimen that was widened in the plane of the bend had more vibration than the other bends when tested under conditions where the entering water had a whirl component of velocity.

Experiments with Model Draft-Tubes.—

(3) The efficiency of the model draft-tubes of 6-in. throat diameter as a device for converting velocity head into pressure head varied between 47% and 65% when the efficiency was defined as the ratio of the head actually recovered to the head available for recovery. There was no appreciable change in the efficiency of the model draft-tubes for changes in rate of flow.

(4) When there was considerable whirl component of the velocities of flow in the draft-tubes, there was a central rotating core in the vertical leg of the tube in which there was a return flow of the water toward the entrance of the tube.

(5) The insertion of a deflector in the model draft-tubes for the purpose of correcting the whirl component of flow was found to be impracticable.

Suggestions for the Design of Elbow Draft-Tubes.—

(6) The vertical leg of an elbow draft-tube should be trumpet-shaped. This shape is just as efficient as any other. It has the advantage over the conical tube that, for a given reduction in mean velocity in a given length of tube, the deceleration is less in the regions of higher velocity.

(7) The following suggestions are offered as a basis for designing the cross-sections of the bend of an elbow draft-tube: (*a*) At 0°, beginning of bend, use a circular cross-section; (*b*) at 22½°, use an elliptical section, with the major axis of the ellipse normal to the plane of the bend; (*c*) at 45°, use an ellipse of greater eccentricity for the inside than for the outside part of the section; and, (*d*) at the end of the bend, use a rectangular section.

(8) The radius of curvature of the inside walls of the bend of an elbow draft-tube should be smaller than the radius of curvature of the outside walls of the bend. The centers of the radii of curvature of the inside and outside walls of the bend should be located so that the distance between the walls diminishes from point to point along the axis of the bend.

(8) A comparison of the results of the tests on pipe bends and draft-tubes, as described in this paper, with the performance of the best elbow draft-tubes described in current technical literature, indicates that, similar to a conical or trumpet-shaped draft-tube of given length and flare in which there is an optimum ratio of the distance between a deflector plate and the bottom edge of the tube to the throat diameter, there probably is an optimum ratio of the distance between the top and bottom walls of the exit of the bend of an elbow draft-tube of given length and flare to the throat diameter of the tube. Further experimentation is needed to establish the optimum ratio to be used in design.

(10) When a guide-vane or "splitter" is used in the bend of an elbow draft-tube, it should extend to about the third point of the bend. The extension of a "splitter" completely around the bend effects no increase in efficiency for direct flow, and causes loss in efficiency for whirling flow. When a bearing partition is used in the lower leg of an elbow draft-tube, it should extend about half way around the bend to help divide the flow between the two halves of the tube when there is whirl component of the filamental velocities.

ACKNOWLEDGMENTS

The writer earnestly wishes to express his appreciation to all those who have helped to make this paper possible. Particular mention should be made of the help and advice of S. M. Woodward, F. T. Mavis, B. J. Lambert, and the late Floyd A. Nagler, Members, Am. Soc. C. E.; Professor Lewis F. Moody, of Princeton University, Princeton, N. J.; D. L. Yarnell, M. Am. Soc. C. E., F. Merryfield, Assoc. M. Am. Soc. C. E., Douglas G. Baird, Jun. Am. Soc. C. E., and Mr. Grant Robley, of the Oregon State Agricultural College, Corvallis, Ore. Draft-tubes for this project were designed under the supervision of Lt. Col. Charles F. Williams, Corps of Engineers, U. S. A., District Engineer, U. S. Engineer Department, at Portland, Ore., and models were authorized to be built and tested at the Oregon State College. The tests of the model draft-tubes were conducted under the direction of the writer, and with the understanding that the experimental data might form a part of this thesis. C. I. Grimm, M. Am. Soc. C. E., was Chief Civilian Engineer in charge of the Bonneville Project.

DISCUSSION

F. T. Mavis,[4] M. Am. Soc. C. E. (by letter).—The author is to be commended for his painstaking work in constructing the model bends and in performing the tests which have been briefly summarized in this paper. He has demonstrated remarkable skill in making transparent model draft-tubes and in shaping and assembling the pyralin sections to be tested.

A quarter-turn draft-tube is no simple conduit. It may be visualized as a combination of a bend and an expanding section of pipe which changes not only in cross-sectional area but in shape as well. This combination, however, is not one that can be investigated readily by studying the peculiar behavior of each part and superposing the flow conditions which would obtain in each part separately. Each of these elements (the bend and the expanding section) has been studied by investigators over a period of more than 60 yr. There is still much to be learned about the behavior of water as it flows in a curved channel and in an expanding conduit, and the investigation of flow in draft-tubes has little more than made its "debut" in the hydraulic laboratory.

The writer proposes to confine his discussion to certain phases of the flow of water in curved pipes which have substantially the same cross-sectional area at the inlet and at the outlet. He will not attempt to discuss the hydraulics of expanding sections nor to dwell upon the combination of bend and diffuser in a draft-tube of the quarter-bend type.

Professor Mockmore has referred to the comprehensive tests on the flow of water in bends which were performed by Messrs. Yarnell and Nagler (22).[3] With reference to investigations of head loss in bends, mention should be made of the pioneer work of Weisbach[5] in Germany, about the middle of the Nineteenth Century; and of the work of Alexander[6] and Brightmore[7] in England; and Williams, Hubbell, and Fenkell,[8] and Schoder[9] in the United States twenty-five to thirty years ago. More recently, investigations on the flow of water in curved pipes and miter bends have been carried on in Germany by Hofmann,[10] Schubart,[11] and others,[12] working in the Hydraulic

Institute, at Munich; in Danzig, by Nippert,[13] and in the United States, by Giesecke,[14] by the staff of the National Hydraulic Laboratory, under the direction of Mr. H. N. Eaton, and by Wallace M. Lansford, Assoc. M. Am. Soc. C. E.,[15] at the University of Illinois. Most of these experiments were conducted on pipes of circular cross-section, although some were made on pipes of square or rectangular section. There is a mass of experimental data which could be collected from many published and unpublished investigations. It would be worth considerable to have these data brought together in a single report, and to have them re-appraised and correlated on the basis of present knowledge of the behavior of water as it flows around a bend.

The problem of the hydraulics of bends has also been investigated in some detail from an analytical, or mathematical, basis. Zur Nedden[16] in a paper on induced currents in fluids published in 1916, presented certain aspects of the problems which merit the mention of his paper in particular. He calls attention to the fact that a bend may perform quite differently depending on whether the flow of the fluid through it is laminar or turbulent. He cites specifically the case of a bend of rectangular cross-section, the inner and outer curves of which were hyperbolic, as causing a lower head loss than a circular bend as long as the flow remained laminar; and that as soon as the flow became turbulent, the hyperbolic bend caused a greater head loss than the circular bend. This behavior, of course, would be apparent if the coefficients of velocity head, representing the excess head loss in the bend, were plotted as a function of Reynolds' number. The particular bend to which Zur Nedden refers was one tested by Grether[17] which in plan was similar to the bend which Professor Mockmore calls Bend No. 2.

To-day, it is generally recognized that a liquid, in flowing around a bend under turbulent flow conditions, moves in a so-called "spiral" or "helical" path, and that the induced currents and attendant impact are largely responsible for excess losses of head in bends. In 1902, the late H. W Brinckerhoff, M. Am. Soc. C. E., discussing[18] a paper by Clarence W. Hubbell George H. Fenkell, and the late Gardner S. Williams, Members, Am. Soc. C. E., explained the fact that a bend offers greater resistance than an equal length of straight pipe on a hypothesis of spiral flow which he described in its essentials precisely as Professor Mockmore and other observers have done. In their closing discussion, the authors of this paper replied to Mr. Brinckerhoff's comments as follows:

> "* * * at one time, one of them [the authors] was disposed to explain certain phenomena on the theory of a spiral motion, but in spite of attempts to locate such motion, no direct experimental evidence of its existence has yet

been obtained, and, though the writers consider that Mr. Brinckerhoff's theory is ingenious and possibly correct, they are not prepared to endorse it."

Transparent model bends, such as those used by Professor Mockmore, permit the observer to see this spiral or helical flow. These transparent models have done much to promote a better understanding and a more intimate knowledge of the phenomena of hydraulics. To-day, this spiral flow in bends can be observed; three decades ago, it was an hypothesis which eminent hydraulic engineers were then " * * * not prepared to endorse * * *."

The intensity of induced currents depends chiefly upon the pressure gradient along a section which is normal to the direction of motion of particles of water in the bends. With slight modification, Equation (4) can be written as follows:

$$p_2 - p_1 = \frac{w}{g} \int_{r_1}^{r_2} V^2 \frac{dr}{r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which $p_2 - p_1$ = the difference in pressure at Points (2) and (1) on a section normal to the flow of water particles; r_2 and r_1 = the radii of curvature of stream filaments at Points (2) and (1), respectively; V = the velocity of flow along any filament the radius of curvature of which is r (and V is, therefore, a function of r); and, $\frac{w}{g}$ = the specific mass of water.

If the width of bend $(r_2 - r_1)$ is small in proportion to the radius of curvature, $0.5\ (r_2 + r_1)$, and if the depth of the channel is large in a direction normal to the plane of curvature; that is, several times $r_2 - r_1$, the velocity will probably be nearly constant and it may be replaced by the average velocity, V_{av}. Under these conditions it may be justifiable to state as a fair approximation that the difference in pressure on the rigid side-walls which are a distance $(r_2 - r_1)$ apart will be, as given by Equation (4),

$$p_2 - p_1 = \frac{w}{g} V^2_{av} \log_e \left(\frac{r_2}{r_1} \right) \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

Co-axial guide-vanes, in general similar to the horizontal partition in Draft-Tube No. 2, may be expected to reduce the head loss in bends for three reasons: (1) The vanes tend to act as baffles and equalize the velocity distribution; (2) by reducing the ratio, $\frac{r_2}{r_1}$, for the individual channels and making it nearer unity than the corresponding ratio for the bend as a whole, the pressure difference, $p_2 - p_1$, is reduced between any two given vanes; and (3), the unbalanced force exerted on a given guide-vane is distributed over a curved plate supported on the side walls of the bend. The efficacy of guide-vanes in reducing losses due to the flow of air in bends has been demonstrated, and bends fitted with co-axial guides have been used in wind tunnels of the return-flow type. In principle, they should also be effective in water conduits although there are certain apparent obstacles in the way of obtaining structural strength at costs low enough to justify the construction of guide-vanes.

The phenomena of flow of water through bends, expanding conduits, and draft-tubes, deserve intensive study in model and prototype. Professor Mockmore's approach through the medium of transparent models leads the hydraulic engineer a long way toward a better understanding of those phenomena.

Jerome Fee,[19] Assoc. M. Am. Soc. C. E. (by letter).—This important paper is distinguished by the experimental technique displayed and the excellent form in which the results are presented. Apart from the special field of draft-tube design, the study is one of great interest in connection with general problems of hydraulics.

The author refers to spiral flow as an important factor. Because of its significance in these experiments and its bearing on diverse subjects, the writer is prompted to discuss at some length the author's "Theory of Induced Spirals in Pipe Bends." Despite the fact that many attempts have been made to explain the phenomena of spiral flow, the writer feels that, even now, a complete and satisfactory analysis is lacking. The purpose of this discussion is not to propose a new explanation, but to call attention to imperfections in the theories which have been advanced from the time of James Thomson (21),[8] in 1876, to Albert Einstein,[20] in 1933, or L. Prandtl,[21] in 1935. It is astonishing how frequently this subject has been referred to in scientific literature and how many outstanding men of science have given it their attention.

There is a close similarity between Thomson's solution and that of Einstein. The author's theory seems to be based on the same general ideas, but the relationship is not so apparent.

Referring to flow in river channels, Thomson writes (21):

> "But the layer of water along the bottom, being by friction much retarded, has much less centrifugal force in any bar of its particles extending across the river; and consequently it will flow sidewise along the bottom towards the inner bank, and will, part of it at least, rise up * * *."

Einstein describes the circulating motion of water stirred in a cup, and likewise finds that the velocity near the bottom and, hence, the centrifugal force, is reduced, from which he concludes that a circulatory motion will occur in radial planes, that is, normal to the general whirling of the water. The writer wishes to take no undue liberties and would prefer to give Professor Einstein's exact words, but is restrained by the formidable phrasing of the copyright clause. It should be mentioned that Einstein was writing for non-technical readers.

It can scarcely be conceived that a reduction in centrifugal force, by itself, will cause a particle to move radially inward toward the center of a curved path. That would be equivalent to saying, "because of a reduction in the force of gravity the particle started to rise." Nevertheless, this method of explaining spiral flow is quite common. To cite one additional example, Richard Hein[22] writes:

---

[19] Asst. Engr., San Francisco Water Dept., San Francisco, Calif.

[20] "The World as I See It", p. 111.

[21] "Aerodynamic Theory", Vol. III, p. 161 (Guggenheim Fund Series, W. F. Durand. Editor in Chief).

> "The layers of water adjacent to the upper and lower sides [actually the top cover and bottom of a closed vortex chamber] experience a breaking effect due to the skin friction, and the resulting reduction in centrifugal force causes flow towards the center of the vortex."

Directing attention next to the explanation given by the author in the paragraphs following Equation (5) where he states that "the pressure at Point *d* will be less than at Point *b*," this opinion appears to be based on the inference that, because of the proximity of the channel walls, the velocity is reduced; consequently, the centrifugal force and, therefore, the pressure are reduced. The writer would expect a high, not a low, pressure at Point *d* in conformity with the usual rule that high pressures go with low velocities. The validity of this rule is proved in an interesting manner by comparing Figs. 6 and 7.

Of the various explanations of spiral flow which the writer has examined, that of L. Prandtl[23] seems the nearest approach to a correct solution. The writer regrets that certain of Prandtl's references are not available, particularly those of which he writes: "The results of experiments recently performed, or about to be performed, should, after some time, permit the definite quantitative determination of the magnitudes involved in the phenomena just described."

Prandtl finds that two distinct cases are involved. One, as the writer understands it, may be illustrated by considering the flow in a curved open channel with frictionless sides, but a rough bottom. In this case, the pressure gradient at the bottom is determined by the pressure gradient of the more freely flowing filaments immediately above. The differential pressure on a bottom particle, not being opposed by as high a centrifugal force as for those above, causes the particle to move radially inward.

In the other case, the curved open channel should be thought of as having a frictionless bottom, but rough curved sides. Prandtl considers that the particles close to the convex wall, by having their velocity reduced, are subject to lower centrifugal forces than adjacent filaments and tend to remain close to the wall. On the other hand, particles at the concave wall, likewise subject to smaller centrifugal forces than adjacent particles, will be pressed away from the wall by such faster moving particles.

Prandtl expresses these ideas with such brevity that the writer feels justified in giving his interpretation, for which he alone is responsible. The writer may have misconstrued or misunderstood the matter, but he is unable to see how spiral flow follows as a result, although the argument for the first case seems the more convincing of the two.

[22] "Investigation of the Thoma Counter Flow Brake", by Richard Hein, *Transactions*, Munich Technical Univ., *Bulletin 3*, pub. in 1935 by Am. Soc. of Mech. Engrs.

[23] "Aerodynamic Theory", Vol. III, p. 161.

The situation in regard to spiral flow seems to parallel a similar problem in aerodynamics where it is necessary in order to explain "lift" to refer to a "circulation" of air about an airplane. To account theoretically for this circulation has been a matter of great difficulty. In a perfect fluid, circulation about an airplane wing would be impossible. In a real, viscous fluid, to account for circulation by the simple statement that the velocity is reduced in the boundary region is quite inadequate.

The writer is of the opinion that all attempts to explain the circulation of water flowing in bent pipes (which circulation, of course, is the distinguishing component of spiral flow), without reference to vortex filaments and surfaces of discontinuity of flow, will ultimately be rejected. The use here of the word, "vortex," has reference not to the entire phenomena of circulation, but to the localized vortices which sometimes determine the nature of the entire flow.

One very interesting feature of the author's study appears to have been the formation of two distinct types of spiral flow. In one type the motion is in circular paths with the fastest moving particles, neglecting longitudinal flow, farthest from the center, or approximately so. This is the type of circulation, as the writer understands it, which Einstein and Thomson describe, and which may exist as one single circulation or two circulations combined, as shown in Fig. 1. On the other hand, such spiral flow as that illustrated in Bend No. 5, Fig. 9(*b*), of sufficient intensity to cause vibration, must be the better known "free vortex" flow in which the velocities increase, approaching the center.

To revert to the first-mentioned type, the writer has before him the typewritten notes recently used in a college class in hydrodynamics. A description of the flow in pipe bends states that "the circulation corresponds closely to that of the Rankine combined vortex, the tangential velocity component being greatest at a point between the center line and the pipe wall, and decreasing toward the center and wall." This is the only specific reference the writer has seen to the distribution of velocities of circulation in pipe bends. It is clear that the distribution differs from that of the free vortex.

These lecture notes explain the circulation by stating that "since these centrifugal forces diminish as the velocity approaches zero, the pressure in the boundary region at the outside of the bend is less than that just within this boundary layer." The writer believes that this is incorrect, as it implies that pressure may manifest itself only as a consequence of centrifugal force.

No one interested in the subject of hydraulics can fail to appreciate the remarkable value, from both the theoretical and practical standpoint, of Professor Mockmore's study.

R. E. B. SHARP,[24] ESQ. (by letter).—It is noted that the losses for Bend No. 5 were not included in the tabulation following Equation (22). It would be of interest to have this information. A comparison of Bends

---

[24] Hydr. Engr., I. P. Morris Div., Baldwin-Southwark Corporation, Philadelphia, Pa.

No. 1 and No. 4 as made and tested by the author does not show the true relation. The latter shows the smaller loss, but to give a true picture of the relative advantage of adopting the shape of Bend No. 4 as compared to the circular shape, the same radius of curvature of axis should have been used for both bends. For Bend No. 4, $\frac{R}{d} = \frac{15}{6} = 2.5$, whereas this value for Bend No. 1, equals 1.333. If the loss with Bend No. 1 is corrected from $\frac{R}{d} = 1.333$ to $\frac{R}{d} = 2.5$, in accordance with tests reported by Dr. Albert Hofmann[25], the following approximate values are derived:

$$(a)\ \text{Loss} = \frac{0.15\ V^2}{2\ g}\ \text{(Mockmore)} \times \frac{0.125}{0.16}\ \text{(Hofmann tests with smooth walls)} = \frac{0.117\ V^2}{2\ g}$$

$$(b)\ \text{Loss} = \frac{0.15\ V^2}{2\ g}\ \text{(Mockmore)} \times \frac{0.14}{0.17}\ \text{(Weisbach)} = \frac{0.1237\ V^2}{2\ g}$$

and,

$$(c)\ \text{Loss} = \frac{0.15\ V^2}{2\ g}\ \text{(Mockmore)} \times \frac{0.09}{0.11}\ \text{(Alexander)} = \frac{0.1225\ V^2}{2\ g}$$

The foregoing corrected values compare favorably, from the standpoint of the circular shape, with those obtained by the author for the elliptical shape of Bend No. 4, in which he found the loss to be $\frac{0.13\ V^2}{2\ g}$.

The tests of the model draft-tubes, as presented by the author, are of interest as such. Tests of this nature may serve as guides for the construction of model draft-tubes for tests with model turbines, but should not be used as the bases for the construction of large tubes in the field. The reason for this, of course, is the impossibility of distributing, properly, the flow at the entrance to model tubes. It is noted that although Model Draft-Tube No. 2 gave the most favorable results, the author did not include data as to its dimensions or the area of its various sections. The lack of these data prevents a comparison and study of this design.

The writer does not think that the author is justified in submitting general recommendations for the designs of elbow draft-tubes on the basis of the tests submitted in his paper. His recommendation that the vertical leg be trumpet-shaped is not borne out by his comparative tests (Bend No. 2 as compared to Bend No. 4). Not only is the efficiency of Bend No. 2, with the conical vertical leg, higher than Bend No. 4, with the trumpet-shaped vertical leg, but, in addition, the outflow loss from Bend No. 2 is decidedly greater than that from Bend No. 4, so that if correction for this fact were made, the efficiency of Bend No. 2 would be relatively increased to a value still greater than Bend No. 4.

---

[25] "Loss in 90° Pipe Bends of Constant Circular Cross-Section," by Albert Hofmann, *Transactions*, Munich Hydr. Inst., *Bulletin* (pub. by A.S.M.E.), Fig. 1.

The Company with which the writer is connected abandoned long ago the Prasil principle of uniform deceleration, as it was demonstrated in practice that where the diverging angle of the tube to meet this requirement exceeded allowable values (7° to 8°) the water did not follow the tube walls, and harmful eddies were formed. Any impact plate at the end of the tube alters the conditions, resulting in flow in a radial direction. However, this condition does not apply to the vertical leg of a draft-tube.

Furthermore, the writer cannot agree that the trumpet-shape will reduce the cavitation tendency of the runner. It is true that the throat rings of some turbines of the Kaplan type tend to corrode. This, however, does not extend down into the tube, even with 7° to 8° flare, but appears to be a function of the movable guide-vanes above, as the corrosion is limited to parts in the line of flow from the guide-vanes.

Although a splitter is often beneficial, the author should draw no conclusions on that basis because Draft-Tube No. 2 showed better results with, than without, a splitter. This tube was apparently designed for a splitter, and the areas proportioned accordingly. Removing the splitter greatly increases the areas around the bend of the tube — at the very region where the rate of diffusion should be a minimum.

L. F. Harza,[26] M. Am. Soc. C. E. (by letter).—It seems to be a general principle that water will flow with the least loss of energy if permitted to conform as nearly as possible with its natural tendencies.

The logic of a wide, shallow design, such as Bend No. 4 (see Fig. 3) can be easily demonstrated by projecting a free stream of water tangentially against a curved sheet of metal. The stream will spread out into a thin sheet as deflected around the curve. The writer is surprised, however, at the small reduction in the loss experienced in Bend No. 4, as compared with the conventional elbow, Bend No. 1. It seems possible that considerably more improvement would result from a still shallower and wider section at the bend if not, indeed, a section that is actually flat on top and bottom. The flattening of Bend No. 4 would not seem to be enough to prevent the formation of the double spiral which could hardly exist in a thin wide section.

The saving of head in Bend No. 4 as compared with Bend No. 1 is only the equivalent of the loss occurring in about 8 in. of straight pipe, which would scarcely seem to justify the more expensive construction of the flattened bend in practical pipe manufacture.

In general, the writer is in agreement with the stated draft-tube principles, except perhaps that the vertical cone should be as long as possible, with short-radius elbow and, consequently, a sharp inside curvature. The writer would indeed agree also with this principle were it not for the better results apparently shown by later tests with the long-radius, sweeping elbow which was finally adopted for Bonneville Dam. It is to be regretted that a parallel test of this design, in a 6-in. inlet size, was not incorporated in the author's comparison. Apparently, it was not included because of the development of this design subsequent to the completion of the 6-in. model series.

ELLERY R. FOSDICK,[27] ESQ. (by letter).—The improvements which heretofore have been made in the science of hydraulics as related to power production, have been almost entirely in the field of dynamics and have usually been confined to such equipment as turbines, needle-valves, the velocity-recovering ability of draft-tubes, and intakes to flow lines. Practically no attempts have seemingly been made to improve the design and operating characteristics of such important structures as bends, elbows, and wye branches. The excellent work presented in this paper by Professor Mockmore, therefore, is a valuable addition to the information that is available on the subject of losses in conduit bends.

The losses that result from bends and wye branches in conduits are frequently quite large and seem to justify more consideration than is usually given them. They are of sufficient magnitude in some installations to warrant the expenditure of additional capital for their reduction.

Draft-tubes are normally subjected to very low heads or to a partial vacuum whereas conduit bends and wye branches operate under higher heads. It follows, therefore, that the type of design which is most suitable for a draft-tube may not be practicable for use in conduit bends and wye branches since for this type of structure it must possess mechanical stability under high heads and, at the same time, be justifiable economically.

The improvements that have been made to hydraulic structures, other than bends and wye branches, have reduced the losses occurring in them to such a low point that no material improvements can be expected in the future and, therefore, the only changes which it is likely will be made are refinements that may result in very minor increases in efficiency. On the other hand, the designs of bends and wye branches have not been changed, for the most part, since the inception of conduits, having a circular cross-section, and the losses in these structures are sufficiently large in some instances to justify the expenditure of additional sums of money, in order to improve the designs toward the end of increasing their efficiency and improving their operating characteristics.

General.—In view of the foregoing facts, the writer has conducted an investigation during the past few years similar to that made by Professor Mockmore, to determine the character of the losses that occur in bends and wye branches, whereas the different types of bends investigated by Professor Mockmore were principally suited for use under low heads as contrasted with the types of structure that were studied by the writer for use under high heads.

The passage of a fluid around a bend in a conduit results in a double spiral eddy in which the diversion loss occurs. This eddy is produced as a result of the distortion to the normal distribution of velocity and an abnormal pressure created by the centrifugal thrust of the fluid. These phenomena have been studied by several investigators,[28] and the results of their work have been previously made available to the Engineering Profession through the medium of various technical publications. Consequently, no further discussion of the subject will be given herein.

---

[27] Elec. Engr., Spokane, Wash.

It has been known to hydraulic engineers for some time that the losses resulting from a bend may be decreased materially through the use of a conduit flattened in a plane at right angles to the plane or the bend. Such a structure, however, is suitable only for very low heads and could not be made physically stable for high heads without excessive cost.

In view of these facts, the selection of a design for reducing the losses in conduit bends would be more or less limited to a cross-sectional shape that was circular, or some part of a circle, so that it would tend to maintain its normal contour under high pressures. After much investigation of this problem before the beginning of these tests, it was finally decided to study a bend with a semi-circular cross-section with the shortened diameter lying in the plane of the bend. Such a conduit might be easily constructed for use under high pressures from a circular pipe by merely installing a diametrical partition wall with relatively small vent holes in it, which would transmit the fluid pressure to the side of the partition wall away from the moving column of water. In this manner the hydrostatic pressure of the fluid would be exerted upon a physically stable structure with a circular cross-section, while the dynamic flow would take place through a conduit having a semi-circular cross-section and the partition wall would only have to withstand the forces produced by the dynamic flow of the fluid passing around the bend.

The tests that are described in this discussion were conducted in the Hydraulics Laboratory at Washington State College, Pullman, Wash., using a standard 6-in. pipe for the supply and discharge lines from a 90° test bend. A schematic arrangement of the flow line which was used for these tests is shown in Fig. 20. It will be observed that the supply line was a straight section of 6-in. pipe practically 33 ft long, whereas the discharge pipe was a straight section of 6-in. pipe approximately 16 ft long. The 90° test bends were inserted between these two sections of pipe. The water supply was obtained from a centrifugal pump, and the flow was measured over a triangular weir shown in Fig. 21, which had previously been calibrated within very close limits. The flow was regulated by means of a valve on the discharge side of the pump and the pressure on the flow line and test bend was regulated by means of a valve in the discharge pipe.

Ten measuring sections were laid out along the 6-in. pipe, as shown in Fig. 20. Four piezometers were placed at each of these sections, spaced 90° apart, with two of them lying in the plane of the bend and two in the plane at right angles to the plane of the bend. Each of these piezometers consisted of a $\frac{1}{16}$-in. hole which had been drilled radially into the pipe and reamed with a specially built reamer so that the broken bits of metal were removed from the inside of the pipe at the edge of the hole and also so that the inside edge of the hole was slightly rounded. Figs. 22 and 23 show the supply line and a test bend in place in the flow line and the discharge line.

FIG. 20.—DIVERSION LOSSES IN PIPE BENDS; ARRANGEMENT OF FLOW LINE USED FOR TESTS.

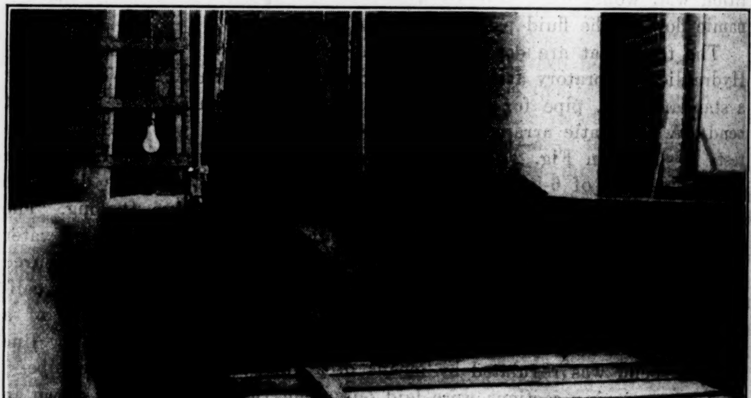

FIG. 21.—CONCRETE FLUME AND TRIANGULAR MEASURING WEIR.

Each of the piezometers was connected to a vertical, glass tube manometer. Throughout the tests of the first two bends, the oscillations of the water column in the manometers were damped by pinching the rubber tubes that connected the manometers to the piezometers. During the tests on the third bend a 6-in. length of capillary tube was placed in series between each manometer and the piezometer for the purpose of damping these oscillations. This latter arrangement was found to be somewhat more satisfactory than the one originally used.

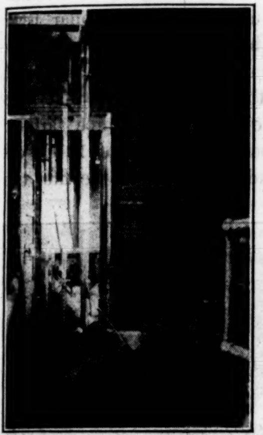

FIG. 22.—SUPPLY LINE AND TEST BEND.

FIG. 23.—DISCHARGE LINE AND CONTROL VALVE.

Three types of 90° bends were tested; the first had a semi-circular cross-section with the same area as a standard 6-in. pipe with the flat side of the semi-circular cross-section at right angles to the plane of the bend

FIG. 24.—FRONT VIEW OF IMPROVED SPECIAL ELBOW NO. 1.

and on the side of the pipe away from the center of curvature. This bend was connected to the pipe having a circular cross-section by means of transition sections. After some preliminary tests had been run on this particular bend another one was constructed, in which the transition and the bend were cast integral in one piece. This bend is shown in Fig. 24.

The next set of tests was run on a standard 6-in. flanged, short-radius elbow. The third set of tests was run when using a semi-circular bend with a cross-sectional shape similar to that in the first set, except that the flattened surface was located on the side of the bend nearest the center of curvature, as shown in Figs. 25 and 26. All the special bends that were tested had the same radius of curvature on the face of the pipe farthest from the center of curvature as the standard bend. A total of 10 564 observations was made of the losses and corresponding flows for the first two of these bends, and 4 496 observations were made of the third one. The results of these observations have been computed and analyzed graphically. A summary of the information which has been obtained follows.

FIG. 25.—END VIEW OF IMPROVED SPECIAL ELBOW NO. 2.

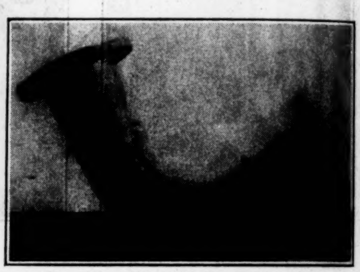

FIG. 26.—SIDE VIEW OF IMPROVED SPECIAL ELBOW NO. 2.

Method of Testing.—Observations of pressure heads were made in the manometers connected only to the right-hand piezometers at the various stations along the flow line, and the equation between the water level in the right-hand and left-hand piezometer at each station was carefully observed throughout the test runs, and recorded at the end of each group of readings. It was found that the equation between the right-hand and left-hand piezometers at any one station remained substantially the same for any given condition of flow, and for this reason it was unnecessary to take readings in both of them.

A group of twenty-five simultaneous readings of the pressure head in the flow line was made for each condition of flow at each station when testing the standard bend and Special Bend No. 1. These readings were made at 10-sec intervals and were found to cover at least one complete cycle of the variations in pressure that were found to be present in the flow line under stable conditions of flow. Consequently, the average of these twenty-five readings for any one flow completed a fairly accurate measure of the normal average pressure head that existed during the particular run.

In making the observations for Special Bend No. 2, the number of consecutive simultaneous readings that was made for any one condition of flow, was reduced to twenty, as this appeared to be adequate for the degree of accuracy desired. The method of reading and the interval of time between readings were the same as for the previous tests.

Due to the limited number of observers it was impossible to read all the piezometers simultaneously and, therefore, it was necessary to take three groups of readings for each test run at each of four adjacent stations. The stations that were read in each group of observations had to overlap in order to determine a continuous hydraulic gradient for the entire flow line; that is, the last, or fourth, station in the first and second groups of readings were the first stations read in the second and third groups of readings.

Observations of the flow were made by taking readings of the head on the weir at 30-sec intervals throughout each test run. The head on the weir was measured with a standard hook-gage and the observations were read to 0.0001 ft. The standard bend was tested under fifteen different conditions of flow with a range of velocity from 2.5 to 7.2 ft per sec. Improved Bend No. 1 was tested with a total of twenty-one different flows, having a range of velocity from 2.4 to 7.1 ft per sec and Improved Bend No. 2 was tested for nine different flows having a range of velocity from 1.7 to 7.5 ft per sec.

Computation of Results.—The diversion loss resulting from the fluid passing around the bend was found by subtracting the total friction loss in the flow line from the total loss in the flow line.

The temperature of the water passing through this flow line during the tests was measured at frequent intervals, and, from this, it was possible to ascertain the kinematic viscosity. With this factor and the mean velocity of the fluid and the diameter of the pipe known, it was possible to compute Reynolds number for the various conditions of flow. This affords a dimensionless parameter for designating the results of these tests so they may be transposed to other hydraulic structures having the same geometric similitude.

It will be observed from Fig. 27, which contains a summary of the information obtained in these tests, that the diversion loss factors for the standard and special bends approach a constant value at about $\mathbf{R} = 250\,000$. This is in accordance with the observations of other investigators and indicates that the loss factors for a Reynolds number of approximately 250 000 may be used with a fair degree of accuracy in computing the losses with a flow having a Reynolds number many times greater.

No observations were made for a Reynolds number much less than 50 000 as this represents a very low mean velocity of flow for a pipe of this size and is a condition that is not ordinarily of importance in the operation of hydraulic structures, therefore, although it may be of theoretical interest, it is not of any practicable importance. It is probable, however, that if these observations had been made, the loss factor curves would have followed approximately the course indicated by the dashed lines on Fig. 27.

Conclusion.—The results of the tests summarized in Fig. 27 indicate clearly that a considerable reduction can be made in the diversion losses that result from the passage of a fluid around a conduit bend by the use of conduits having a semi-circular shape when they are arranged with the flat side at right angles to the plane of the bend. This is in agreement with the conclusions reached by Professor Mockmore and others that the losses resulting from the passage of a fluid around a conduit bend can be reduced by flattening the structure in the plane of the bend. The semicircular shape of the conduit bends that have been used in these tests create a redistribution of the fluid velocity that minimizes the losses by reducing the unbalance of pressure resulting from the centrifugal thrust of the fluid column and by decreasing the resistance to flow around the bend on the side nearest the center of curvature. The types of bends tested by the writer were designed to withstand high heads in addition to reducing the losses whereas the bends that were tested by Professor Mockmore were designed for use under low heads. As a result there is not sufficient similarity between the different bends that were tested to permit a comparison of the results.

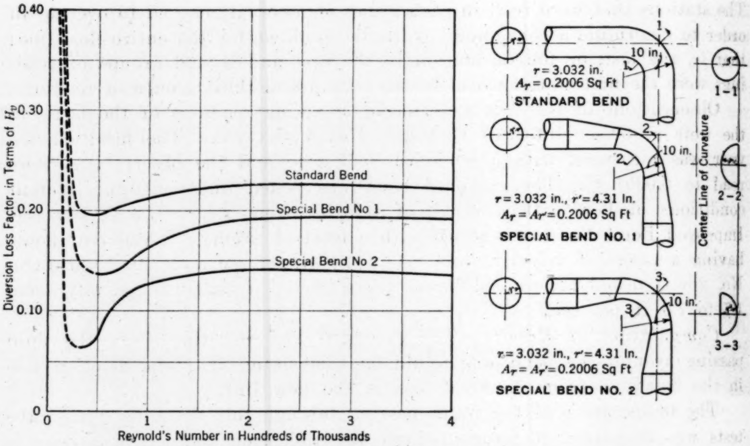

FIG. 27.—COMPARISON OF DIVERSION LOSS FACTORS FOR VARIOUS TYPES OF CAST-IRON FLANGED 90-DEGREE BENDS

The loss factors for Special Bend No. 1 with the flat side radially outermost were found to be materially less than the corresponding loss factors for a standard bend of circular cross-section having the same cross-sectional area and radius of curvature. The loss factors for Special Bend No. 2, which had the flat side radially innermost, were found to be much less than the corresponding loss factors for Special Bend No. 1 and very much smaller than the losses for the standard bend.

The construction of a conduit bend having a semi-circular shaped passage for the moving fluid is feasible for operation under high heads with the shell and partition design. In this type of structure a circular pipe having approximately twice the required cross-sectional area, and designed to withstand the fluid pressure, has a relatively thin longitudinal partition wall that is secured in the pipe in a diametrical position in the plane at right angles to the plane of the bend. Relatively small holes in the partition wall transmit the fluid pressure to both halves of the conduit with the result that the only force acting on the partition wall is the relatively small pressure produced by the dynamic action of the fluid.

Acknowledgment.—The facilities of the Hydraulics Laboratory at Washington State College were made available for these tests by H. V. Carpenter, Dean of the Engineering School, and M. K. Snyder, M. Am. Soc. C. E., Head of the Civil Engineering Department. J. G. Woodburn, Assoc. M. Am. Soc. C. E., contributed much of his time and energy in assisting with the work that was done in the Laboratory, and it was largely through his efforts and co-operation that these tests were successfully completed.

HOWARD L. COOPER,[29] ESQ. (by letter).—The type of experimentation developed by Professor Mockmore will have a marked impression on the future of hydraulic machines and structures. This fact has certainly been demonstrated in the turbine and draft-tube laboratory of the U. S. Army Engineers, at Portland, Ore., in connection with the Bonneville Project. The writer wishes to discuss further some of the statements made by Professor Mockmore and to give a little more information on the draft-tube report, especially pertaining to the tubes that were tested after the work was finished at the Oregon State Laboratory and moved to the U. S. Engineer Laboratory, at Linnton, Ore.

Figs. 28 and 29, are submitted as evidence of the study that was started in an effort to find a relation between diameter of jet, radius of curvature, and angle of flare of a jet of water passing around a curve on a flat plate. Such a jet represents the natural flow as it probably offers less resistance than any other method of changing the direction of flow through 90 degrees. It is very easy to visualize the double spiral if one pictures this fan-shaped jet folded up from each side upon itself until it is confined in a 90° elbow. The major losses are then the energy required to form the double spiral and also the internal friction caused by the different strata of the whirl meeting with different relative velocities with respect to the initial flow.

The writer agrees with Professor Mockmore that Elbow No. 4 should be the most efficient, as the flattened shape conforms more nearly to the fan-shaped jet shown in Fig. 28 and Fig. 29. The double spiral is dissipated to a certain degree while making the turn. Fig. 30 shows a jet of water passing around a standard elbow with the jet smaller than the elbow inlet; it can be clearly seen how one-half the double spiral begins to develop.

---

[29] Office of Div. Engr., North Pacific Div., U. S. War Dept., Portland, Ore.

Referring to the elbow studies, the writer is convinced that a slow-motion study of elbows, possibly using additional shapes, would show many interesting phenomena and possibly develop some ideas that would be a real contribution to the study of hydraulics.

FIG. 28.

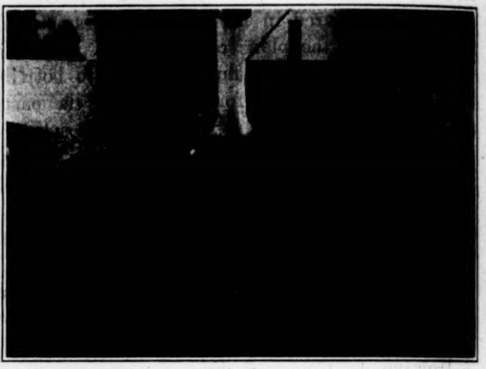

FIG. 29.

Referring to the functions of a draft-tube, the writer wishes to take the liberty of discussing the advantages in a little more detail. The velocity of the water is reduced after leaving the turbine runner, but in doing so it maintains a seal at all times and lowers the absolute pressure directly under the runner and, therefore, increases the total effective head on the unit. A poor draft-tube that does not maintain this seal loses this gain in velocity head and, therefore, reduces the output of the turbine, and also frequently causes serious vibration, which naturally reduces the life and mechanical efficiency of the unit.

FIG. 30.

The location of the center line of the runner above the tail-race is an important feature. Francis wheels can be placed much higher than those of the propeller type. A very careful study must be made of propeller type settings with respect to their elevation above tail-water, as the location depends on the proper combination of the plant, σ, specific speed, ϕ, and the general design of scroll and draft-tube, in order to prevent cavitation at the higher loads and low tail-water conditions. ($\sigma =$ the cavitation coefficient $=$ the ratio of the maximum possible pressure reduction within the runner without vaporization of the water, to the total effective head on the turbine. Plant σ is distinguished from Field σ by a suitable factor of safety. The ratio of the peripheral speed of the runner to $\sqrt{2\,g\,H} = \phi$.) Cavitation not only affects parts of the runner blades and throat liners, but sets up detrimental vibrations in the unit and the structure.

A draft-tube also should have enough velocity at the exit, together with the hydraulics of the tail-race, to keep the velocity high enough to clear the tail-race without the building up of undue head.

In large draft-tubes the writer makes the following recommendations based upon experimental observation. In addition to the horizontal splitter, at least two vertical splitters are suggested; also, the placing of six or more vertical, stream-lined struts in the exit half of the horizontal leg, the spacing to be arranged by experiment. These struts will cause the water to seal the exit with a uniform discharge and, therefore, increase the re-gain within the draft-tube.

TABLE 5.—HEAD, IN FEET, REQUIRED TO FORCE A FLOW OF 0.997 SECOND-FOOT THROUGH DRAFT-TUBE NO. 2

Description	ANGLE OF WHIRLING COMPONENT AT ENTRANCE	
	30°	40°
Without struts	0.4062	1.709
With struts, Arrangement No. 1	0.3971	1.695
With struts, Arrangement No. 2	0.3821	1.683

The information contained in Table 5 is taken from experimental data, Draft-Tube No. 2 being operated with, and without, the vertical struts in the horizontal leg near the exit (see Fig. 31).

Draft-tube passages that do not allow the water to flow smoothly reduce the re-gain in velocity head, and this method of experimentation, together with the use of slow motion pictures, possibly will enable most of the internal cross-currents to be checked and corrected, thereby increasing the re-gain in velocity head. The writer suggests that a material of practically neutral buoyancy be used in the water instead of the injection of air, because the air bubbles will flow toward the upper surfaces and will not give a true pattern of the flow. Besides, the air bubbles change the specific gravity of the liquid used, which change can not be conveniently compensated, and no doubt will cause Pitot tube velocity readings to be incorrect.

After weeks of searching, the writer found a hardwood granular sawdust that would give a true pattern after being soaked in water for about 24 hr; it would neither float nor sink, and being practically the same weight as water, did not affect the specific gravity of the liquid. This material photographs very well in slow motion pictures. The writer also agrees that any attempt to simulate the flow from a water-turbine runner by mechanical means is useless. An homologous model runner should be used in all scroll-case and draft-tube studies. There is no doubt in the writer's mind about the statement that every draft-tube should be designed especially for its own setting and turbine.

FIG. 31.—ARRANGEMENT OF ELECTRODES IN DRAFT-TUBE TESTS.

The writer would carry the increasing diminishing degree of the area in the elbow a little further and reduce the sections around the bend, giving the flow a slight acceleration. All model tests showed that when the velocity was slightly accelerated, very smooth flow resulted. This can also be observed by inspecting Bend No. 5, in Fig. 9(*b*) of the paper. After the flow begins to decelerate, it moves in various directions, but while it is accelerating, it is noticeably smooth.

A method of measuring the efficiency of elbows and draft-tubes when the water has a whirling component is very important and such measurement could be accomplished in at least three ways: (1) One with a small tube with two holes in the sides located diametrically opposite and then placed into the flow with the holes 90° from the line of flow; (2) another method would be to use the outside piezometers and correct for the centrifugal force of the whirling body of water; and (3) the third suggestion would be to use the method developed by the Reclamation Bureau and used in the War Department laboratory at Portland; that is, find the entrance loss in the entrance tube without the draft-tube in place for the various whirling components, and then operate the entrance tube in conjunction with the elbow tube. Combining results:

$$\text{Draft-tube efficiency} = \frac{\left(\frac{C_2}{C_1}\right)^2 - 1}{(C_2)^2} \dots\dots\dots\dots\dots (28)$$

in which C_1 = the coefficient of discharge of the entrance tube; and C_2 = the coefficient of discharge of the entrance tube, together with the elbow tube. In all experiments the flow should be corrected to one common quantity by using the coefficient of discharge method; that is, find the coefficient of discharge and substitute back in the orifice formula, using a constant rate of discharge, Q, for the final data. This may not indicate large variations because the efficiency varies little with a change in the quantity; however, it does make the data comparable.

There is no doubt that the most satisfactory method of checking the operating advantages of draft-tubes would be to run them on a model turbine that is equipped with an accurate dynamometer. This will give the relative operating efficiency of the various combinations, which is what is required in the final analysis. The following comments are offered on the draft-tube models designed by the U. S. Engineer Department.

Draft-Tube No. 1.—The principle of the fan-shaped jet, as shown in Figs. 28 and 29, was applied to this design within the practical limits of the economical center spacing of units in the power house. The elbow flow was very smooth; however, the high velocity at the extreme sides caused a reversal of flow in the center and near the top of the horizontal leg, and in many places there were no-velocity areas.

Draft-Tube No. 2.—This tube was patterned in general after the Ryberg-Schwerstadt tube, the unit being as near to the Bonneville size and power as any other Kaplan turbine then in operation. As the first tests show, in Table 6, this tube gave fairly good results. The tube was then taken to the U. S. Engineer Laboratory, at Linnton, Ore., and, as a result of slow motion pictures and general observation, several alterations were made: (*a*) The deceleration around the bend was changed to a slight acceleration; (*b*) the top of the vertical leg near the bend was lowered to fill a no-velocity area; and (*c*) the angle of the elbow sides was reduced with respect to the center line. All these changes indicated a marked improvement in the flow conditions and, based on the same method of testing as that done under the direction of Professor Mockmore, showed an average efficiency of 70.0% an increase of about 5 per cent.

The fact that this increase was due to the visual study would indicate that many additional improvements would be possible with added research.

This tube would give very good operating results on a turbine having a small whirling component in either the forward or backward direction. The elbow is too short and the splitter too high in the vertical leg for a wheel having a large whirling component which would set up violent disturbances and reduce the efficiency. All tests definitely showed that wheels giving a large whirling component should have the splitter located above one-third of the way around the board as recommended by Professor Mockmore.

* Data, October 17, 1934.

Draft-Tube No. 3.—This tube incorporated the flat jet idea that was used in Tube No. 1, together with the spreading-tube principle as used by some turbine manufacturers. The results were practically identical to those found in Tube No. 1, and the flow conditions within the tube were quite similar.

Draft-Tube No. 4.—This tube was designed and tested by Professor Mockmore. The writer did not see it operate, and, therefore, will make no comment on general operation.

Draft-Tube No. 5.—This draft-tube (not shown in Professor Mockmore's paper) was designed so that the entire whirling component was transferred into velocity head without the use of splitters; only one vertical splitter was used and that was for structural reasons. The one model that was made showed very good efficiency. No alterations were made, due to the lack of time, but the writer is confident that, with several alterations and re-proportioning, the tube could be made into an excellent draft-tube. The cost of construction should not exceed the cost of splitter tubes.

An interesting phenomenon occurs when under operation; that is, no matter whether the entrance whirling component is 1° or 50°, the flow is evenly divided between the two exit channels with no eddies or high velocity areas. The tail-race is exceedingly smooth under all load conditions. The slow motion pictures showed that this double spiral was completely dissipated before passing around the bend.

* C_2 = coefficient of discharge.

The writer cannot see why Tube No. 4 which contains many of the author's recommendations for designs of draft-tubes, should show a lower efficiency than the Tube No. 2 which is similar in general shape but does not contain any recommended designs. The trumpet-shaped vertical leg or straight-line deceleration showed less efficiency when installed on Tube No. 2 than the straight cone. The data given in Table 7 are offered as evidence.

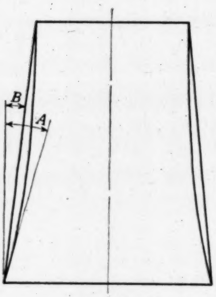

FIG. 32.

The writer agrees that a sudden deceleration near the runner may cause cavitation, but he does not believe that the difference between the straight cone and the trumpet-shaped vertical leg would be large enough to cause any trouble. It would be possible, however, to set up eddy and shock losses at the lower end of the trumpet-shaped vertical leg if the deceleration was relatively large because the angle of flare (Angle *A*, Fig. 32) would exceed the angle that water will follow without leaving the surface, where a smaller angle (Angle *B*, Fig. 32), might be satisfactory. The trumpet-shaped vertical leg has one decided advantage (if Angle *A* is not too large) and that is that this change in shape will naturally conform to the widening required within the bend.

Table 8 is submitted as evidence that for a flow that is either straight or with a small whirling component, the location of the splitter as shown on Tube No. 2 is the most efficient. There is a pos-

* C_2 = Coefficient of discharge.

sibility that with the splitter removed the change in rate of deceleration caused the drop in efficiency. The fin on top of the splitter would no doubt be impractical, according to the author, due to the large variation in whirling component; but no doubt it could be used to good advantage in pipe elbows with a fixed angle of whirl.

The writer agrees that the whirling component changes from forward to backward in the Francis type of turbines depending upon load conditions, but for Kaplan propeller types within the normal range of specific speed this component is always forward in the direction of the propeller rotation. There is belief in the writer's mind that one could capitalize on this phenomenon and the energy within this rotating body of water regained in the form of useful work (Draft-Tube No. 5, for example).

The writer can not subscribe to the belief expressed by Professor Mockmore regarding a central rotating core in the vertical leg moving toward the entrance of the tube. This may have been possible when the core was composed mostly of air, but in all tests at the Portland laboratory where a neutral buoyancy material was used to give the flow pattern, no reversal of flow was observed under any operating condition.

Considerable advance in the art of constructing pyralin models has been made in the past few years. One arrangement that gave very accurate results without wrinkling or discoloring the pyralin consisted of an electric oven, thermostatically controlled, into which the moulds for forming the models were placed. The moulds with the pyralin sheets in place were forced together by a hydraulic ram operated from the outside, one side of the oven containing a mica window for observation. After the moulds were pressed together completing the forming operation, the oven was allowed to cool before they were removed. Motion picture cameras taking 64 frames per sec are fast enough to photograph the flow in models of this size. From experience, it is recommended that they be taken at night under artificial light.

The longer draft-tube should be the most efficient for two important reasons: (1) It effects a greater re-gain in velocity head; and (2) it allows whirling and elbow disturbances a longer passage in which to straighten out and make a better seal at the exit of the tube.

The writer would like to make the following suggestion for design of elbow draft-tubes: Carry the circular and elliptical sections down as far as possible in the vertical leg; in order to make the bend, select the inside and outside radii by experience and model testing; reduce the section areas slightly, allowing the top and bottom to conform to the fixed radii and the sides to the correct areas, the flow lines, of course, to be fair at all times. The flow can be decelerated finally in the horizontal leg. In large units install at least two vertical splitters in the horizontal leg and extend them about one-fourth of the way around the bend, one horizontal splitter which does not extend more than one-third of the way around the elbow, and six or eight vertical stream-lined struts in the exit half of the horizontal leg.

The following list gives an idea of many features that could possibly be improved by visual studies of draft-tubes for various specific speeds and types of wheels over a wide range of operating speeds: The location of the splitter; the shape of the splitter; the number of vertical splitters; the proper relation of deceleration and acceleration; shock and eddy losses; no-velocity areas; high velocity areas; reversals of flow; cavitation; vibration; straight-line or parabolic deceleration; minimum exit velocity; use of stream-lined vertical struts; ratio of total depth to diameter of wheel; and inside and outside radii of elbow.

C. A. Mockmore,[30] M. Am. Soc. C. E. (by letter).—There is ample reason to agree with Professor Mavis that "the investigation of flow in draft-tubes has little more than made its 'debut' in the hydraulic laboratory." The findings made in this study and the suggestions made for the design of draft-tubes are not regarded as final. In this day of research, even the validity of the Newton law of gravitation is subjected to careful scrutiny.

Mr. Fee refers to Fig. 1 and the discussion following Equation (5), and states that he "would expect a high, not a low, pressure at Point *d* in conformity with the usual rule that high pressures go with low velocities." This belief is apparently based on the Bernoulli theorem, and would be correct for a single particle of water, but in Fig. 1 two different particles are under consideration.

Consider a case of two particles of water such as at Points *b* and *c* of Fig. 1 if they are moved up stream a reasonably short distance, say, 1 ft. Would the two particles be subjected to pressures of equal magnitude? Certainly the particle near the center of the pipe would have a greater velocity head than the one near the walls of the pipe. If the two particles possessed the same total energy the pressure near the walls would be greater than at the center of the pipe. This seems questionable. If there is a difference it could not well be detected by the pressure orifice of the Pitot tube used in these experiments. If the pressures are practically uniform across the pipe section and the filamental velocities are highest near the center of the pipe then the highest total energy content would be near the center of the pipe, as indicated for Section 1 of Bend No. 1, Fig. 7.

Now consider particles at Points *b* and *d* of Fig. 1 again, just before they start around the pipe bend. Suppose each particle possesses approximately the same pressure head, but different velocity heads. Then an instant later each particle starts its course around the bend. Particle *b* will have the greater centrifugal force and thus will tend to crowd Particle *d* toward the center of curvature. Two fundamental conditions were necessary to induce the spiral, namely, the presence of a curve in the channel to induce centrifugal force, and a difference between filamental velocities near the center and walls of the conduit.

Mr. Sharp thinks that the writer is not justified in submitting general recommendations for the design of elbow draft-tubes on the basis of the tests submitted in the paper. Of course, the recommendations are not drawn from the tests described only, but from other sources, such as a review of the literature, inspection of turbines in operation and repair, and from visits to various turbine laboratories where scores of model draft-tubes of almost every conceivable shape have been tested. For example, at one commercial laboratory visited in 1932, a test was described in which a movable false bottom was installed in an elbow tube such as one might imagine for Tube No. 2, Fig. 12, between Sections 5 and 10, so that the vertical dimension along Section 7 (termed the Δ-distance in this discussion) might be reduced. In the test referred to, the tube efficiency was increased by reducing the Δ-distance.

---

[30] Prof. and Head, Dept. of Civ. Eng., Oregon State Coll., Corvallis, Ore.

The data on the areas at various sections of Draft-Tube No. 2 are given in Table 2, and are compared to a 6° conical tube.

Mr. Sharp states that tests on model draft-tubes should be used as a guide for tests with model turbines " but should not be used as the bases for the construction of large tubes in the field." It would be difficult to convince many engineers interested in model research that such work had no value in relation to the design and construction of large water-turbine developments. Very little experimental data can be had on such large developments as that on the Columbia River. Changes are difficult and expensive to make, and measurement of flow of water through the turbines is especially troublesome and questionable in accuracy.

The trumpet-shaped vertical leg of the draft-tube need not extend far from the exit of the turbine runner, so that the allowable values of flare are not exceeded, somewhat as an easement spiral is placed on a railroad curve. Suppose the efficiency of Draft-Tube No. 2 were higher than that of Tube No. 4, as Mr. Sharp points out, one wonders why he did not show experimental evidence or other proof, that it could have been due to the Prasil vertical leg. Experiments of Hofmann (8),[3] Gibson and Labrow (30),[3] and Andres (31),[3] indicate that the trumpet-shaped tube has as high, if not higher, efficiency as a straight cone. As indicated in Figs. 18 and 19, there was greater dead-water space in Tube No. 4 than in Tube No. 2. Surely this should not be ascribed to the Prasil vertical leg. Would it not more logically be due to too great a Δ-distance? In this same connection Mr. Harza suggests that considerably more improvement would result from a still shallower and wider section of a pipe bend, which would call for additional lessening of the Δ-distance of an elbow tube.

The loss in flow through the experimental pipe bends appears to have interested, not only Mr. Sharp and Mr. Harza, but brought forth the description of an interesting experiment by Mr. Fosdick. His special Bend No. 2 gave the most favorable loss factor, and, in general, seems to verify the writer's suggestion, (7(*c*)), for the design of the bend of an elbow draft-tube.

It is regretted that Mr. Cooper did not submit the design of the Draft-Tube No. 5, which showed such fine characteristics in operation. He states that it " was designed so that the entire whirling component was transferred into velocity head." The test would really be met when this whirling component is transferred into effective head on the turbine.

Mr. Cooper submits Table 8, as evidence that the splitter should extend completely around the bend as in Draft-Tube No. 2, ostensibly to refute Conclusion (10), and then proceeds to give his own suggestions for design to include "one horizontal splitter which does not extend more than one-third of the way around the elbow." No reason is given for the apparent inconsistency.

A NEW THEORY OF RAIL EXPANSION

By Alfred Africano,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Chester F. Gailor, E. F. Kenney, C. W. Baldridge, George W. Hunt, Frank B. Walker, Arthur N. Talbot, Randon Ferguson, A. N. Reece, G. M. Magee, H. D. Hussey, and Alfred Africano.

Synopsis

The change in length of a rail resulting from a change in temperature is ordinarily taken as the product of the coefficient of linear expansion times the length times the change in temperature. The action of the ties in resisting longitudinal movement of the rail is neglected.

For a 33-ft rail, with ordinary track construction, the resulting error is less than 2%, and, therefore, may be justly neglected; for a 66-ft rail, however, it may be from 10% to 40%, depending upon how securely the rail is fastened to the ties; and for the long continuous welded rails, the error is so great that it is evident that tie resistance must be taken into account.

In the following analysis of the problem, formulas are developed which include the action of the ties, and, in addition, the effect of joint restraint. The resultant theoretical rail expansions are in good agreement with the general observations made on the German railroads, and the careful measurements made on four half-mile length rails in the Delaware and Hudson track, at Mechanicville, N. Y.

Notation.—The letter symbols in this paper are introduced in the text as they occur and are summarized for reference in Appendix I. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials"[2] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

The coefficient of linear expansion, n, for hard steel is equal to 0.0000073 in. per degree Fahrenheit per in. of length[3]. Therefore, the free expansion

of a rail, expressed as a formula, is,

$$\Delta l_f = n \, \Delta t \, l \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which l = half the length of a rail; and Δl_f = change in length, due to a temperature change, Δt, when the rail is free to expand. If this expansion is prevented by fixing the ends of the rail, the resulting uniform stress, s, in the rail is, in pounds per square inch,

$$s = E\delta = E\frac{\Delta l_f}{l} = E \, n \, \Delta t \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which δ = unit strain, in inches per inch; and E = modulus of elasticity. For $E = 30\,000\,000$, $s = 219 \, \Delta t$, or the stress is 219 lb per sq. in. for every degree change in temperature. It should be noted that this stress is independent of the length of the rail.

If $\Delta t = 100°$ F is the rise in temperature over that at which the rail was laid, the stress would be 21 900 lb per sq in.; and if the rail section were a 100-lb A R A-B[4], with a cross-sectional area, $A = 9.85$ sq in., the force, F, required at each end to prevent expansion would be $F = sA = 21\,900 \times 9.85 = 216\,000$ lb. To develop this force in one-half the length, l, of a 33-ft rail, with the tie spacing, c, equal to 22 in., would require the average tie resistance to longitudinal movement, T, to be: $T = \dfrac{216\,000 \times 2 \times 22}{33 \times 12} = \dfrac{216\,000 \text{ lb}}{9 \text{ ties}}$ = 24 000 lb per tie.

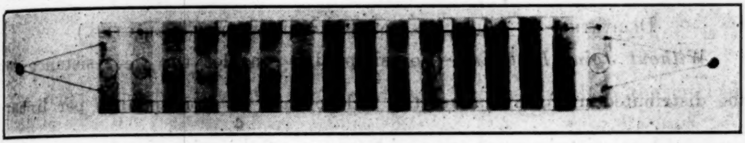
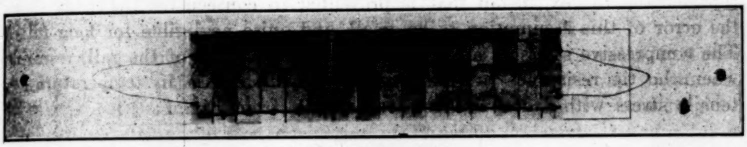
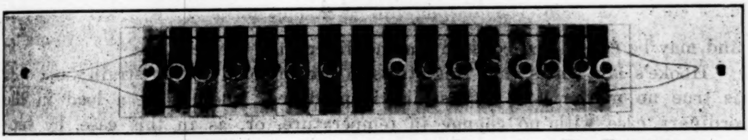
Since it is improbable that one rail-fastening and the tie will develop a resistance of 24 000 lb, unless set in concrete, a 33-ft rail expands quite freely; but when several rails are made continuous the average tie resistance drops to an amount that can be developed reasonably, and the fixed-end condition is approached. Table 1 illustrates how the average tie resistance required to prevent expansion varies inversely as the length of the rail.



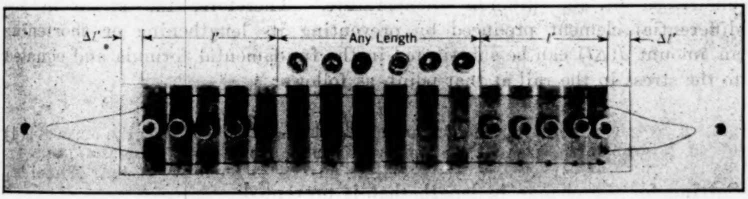
(*a*) ORIGINAL LENGTH OF RAIL



(*b*) FREE CONTRACTION



(*c*) CONTRACTION DECREASED BY LONGITUDINAL RESISTANCE, NOT UNIFORM



(*d*) NO LONGITUDINAL RESISTANCE REQUIRED OF TIES IN THE FIXED PART OF THE RAIL

FIG. 2.—MODEL SHOWING THAT RESISTANCE TO LONGITUDINAL MOVEMENT DEVELOPED BY THE RAIL FASTENINGS NEAR THE ENDS CAN BE SUFFICIENT TO PREVENT CONTRACTION OF THE REMAINDER OF THE RAIL.

The free ends of the continuous rail will always expand a certain extent. To determine this actual expansion for any length of rail, and for any degree of tie resistance, it is simply necessary to determine how much expansion is prevented, and to subtract that from the free expansion. The concept of the increasing resistance to longitudinal movement, from zero at the free ends to a maximum when N ties completely fix the rail, is illustrated in Fig. 1.

It may be demonstrated very effectively with the model shown in Fig. 2, which consists of two elastic bands fastened to cardboard strips which represent equally spaced sections of the rail base. By first stretching the elastics, then placing weights on the strips to obtain various degrees of longitudinal resistance (rail-fastenings), and, finally, releasing the ends, the action will closely approximate that of a rail following a drop in temperature. Using compressed springs instead of the elastic bands would illustrate the case in expansion.

DERIVATION OF FORMULAS FOR EXPANSION (OR CONTRACTION)

Without Joint Restraint.—For simplicity consider the tie resistance to be distributed uniformly along the rail so that $\frac{T}{c}$ is in pounds per linear inch. (A solution by summation of the terms of the arithmetical progression representing the expansion that is prevented in consecutive tie spans shows the error of this assumption to be small, and quite negligible for long rails.) The compressive stress at any point, x in. from the end of the rail, resulting when the tie resistance prevents expansion with a rise in temperature (or tensile stress with a drop in temperature), is, from Fig. 1:

$$s_x = \frac{T\,x}{c\,A} \quad \text{(3)}$$

and may be considered constant in the differential element, dx.

Hooke's law states that this stress is proportional to the strain; and this is true no matter how that strain is produced, whether by a load in the ordinary case with no change in temperature, or, as in this case, by suppressing part of the normal change in length required to leave the rail unstressed at the different temperature. Therefore, the strain in the differential element produced by preventing its lengthening or shortening an amount $d(\Delta l)$ can be substituted in the fundamental formula and equated to the stress in the rail at that point, as follows:

$$s_x = E\,\delta_x = E\frac{d\,(\Delta\,l)}{dx} = \frac{T\,x}{c\,A} \quad \text{(4)}$$

Solving for the change in length that is prevented,

$$d\,(\Delta\,l) = \frac{T\,x\,dx}{c\,A\,E} \quad \text{(5)}$$

The total expansion (or contraction), Δl_r, that is resisted in the half-length, l, is now found by integrating between the limits, $x = 0$ and $x = l$, or,

$$\Delta\,l_r = \int_0^l \frac{Tx\,dx}{c\,A\,E} = \frac{T\,l^2}{2\,c\,A\,E} \quad \text{(6)}$$

(This result of integrating Equation (6) can be obtained without the use of calculus by noting that the sum of all the suppressed unit changes in length is equal to the area of the triangle which represents them as changing uniformly from zero at the free end to a maximum when the rail is fixed. However, it is best to use calculus to illustrate the general method to be used in case the resistance to longitudinal movement of the rail is found to be some empirical curve rather than the simple straight-line variation assumed in this analysis.) The net expansion is the free expansion minus that which is prevented, or,

$$\Delta l = \Delta l_f - \Delta l_r = n \Delta t \, l - \frac{T \, l^2}{2 \, c \, A \, E} \quad \ldots\ldots\ldots\ldots\ldots (7)$$

The maximum end expansion occurs when l becomes equal to the critical length,

$$l' = \frac{E \, n \, \Delta t \, A \, c}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

required to develop the longitudinal force, $F = E \; n \; \Delta t \; A$, which fixes the rail thereafter, so that there is no further increment in the total expansion. If this is not sufficiently obvious from Fig. 1, a convincing proof may be obtained by setting the first derivative of Equation (7) equal to zero for a maximum, and solving for l. Consequently, the tie resistance, T (which is simply a frictional reaction opposing any movement), does not come into action at all in any additional length of rail placed between the critical lengths, l', at each end, as the model action shown in Fig. 2(d) clearly demonstrates.

Substituting the value of this critical length in Equation (7) results in the following simple expression for the maximum end movement of a rail without joint restraint:

$$\Delta l'_{\max} = \frac{E \, n^2 \, (\Delta t)^2 \, A \, c}{2 \, T} = \frac{\Delta l'_f}{2} \quad \ldots\ldots\ldots\ldots\ldots (9)$$

Stated as a theorem:

Theorem 1.—For free ends, the maximum expansion at each end of a long continuous welded rail is one-half of what the free expansion would be in the length that is required to fix the rail.

That this is what should be expected is evident when it is considered that the expansion varies from its normal unit free expansion at the end of the rail, uniformly, down to zero at the point along the rail where the force (independent of the length) required to fix it becomes fully developed.

Note that Equation (9) shows that the maximum expansion: (1) Is independent of the length of the rail; (2) varies as the square of the temperature difference for a given track; and, (3) for different tracks, varies inversely as the tie resistance. This is quite a departure from the time-honored method of computing allowable gaps for 33-ft rails. That the actual expansion follows Equation (9) in principle is strongly supported by the careful observations made on four continuous rails, each about 2 600 ft long, at Mechanicville, and the general observations made in Germany and other countries where long rails have been installed.

Example 1.—For the case in which $n = 0.0000073$, $\Delta t = 100°$ F; $c = 22$ in.; $T = 1\,000$ lb per tie; $A = 9.85$ sq in.; and $E = 30\,000\,000$ lb per sq in.: $F = 216\,000$ lb; $N = 216$ ties; and $\Delta l'_{max} = 1.74$ in. This maximum expansion would occur at each end of a continuous rail, $2l' = \frac{216 \times 22 \times 2}{12} = 792$ ft long. For any longer rail, the additional length would be fixed completely against expansion, so that the total expansion at the ends would remain the same.

Expansion of Rails Shorter Than the Critical Length.—For lengths less than 792 ft, the net expansion can be derived from Equation (7), which reduces to,

$$\Delta l = 0.00073\, l - (0.077 \times 10^{-6})\, l^2 \ldots\ldots\ldots\ldots\ldots (10)$$

for this case.

The theoretical expansions from this equation for various lengths are given in Table 2 to show what can be expected under the assumed conditions.

TABLE 2.—THEORETICAL EXPANSION AS COMPUTED BY EQUATION (10)

6.....	198	54	0.87	0.11	0.76	30...	990	270	3.48	1.74	1.74

* $\Delta l'_{max}$.

The maximum expansion varies inversely as T. Therefore, a value of $T = 5\,000$ lb (claimed possible in certain types of track construction), instead of the $T = 1\,000$ assumed, would give a result only one-fifth as great (that is, 0.35 in.) and $N = 43$ would be the number of ties required on each side of the middle of the rail to prevent further expansion for longer rail lengths. For this case the critical length, l', would be 79 ft.

There probably would be a slight movement of the tie proportional to the resistance for so high a value of T. To show a possible cause of discrepancy in the observed and theoretical rail expansions, as described in this paper, and to show also that it is probably negligible if H, the modulus of horizontal resistance, is about the same as u, the vertical modulus of foundation[5], the following calculation is given. (The modulus of foundation, u, is the load per unit length of the rail required to produce a vertical deflection of the foundation equal to unity. By analogy, the modulus of horizontal resistance, H, is the force per unit length of the rail required to produce a horizontal deflection of the foundation equal to unity.) If, on the average, each tie moved about the same distance to develop its value of tie resistance, T, the additional movement of the end of the rail would be:

---

[5] Introduced in the First Progress Report of the Special Committee on Stresses in Railroad Track, *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1191.

$$\Delta l_H = \frac{T}{c\,H} \qquad (11)$$

Substituting $T = 5\,000$, $c = 22$ in., and $H = u = 1\,500$ lb per in. per in. (an average value), in Equation (11), the additional movement is found to be only 0.15 in. The total expansion at the end is, then, 0.35 + 0.15 = 0.50 in., for this case.

A length of continuous rail, 200, 400, or even 1 000 ft long, would give the same theoretical expansion (0.50 in.), that is calculated for this 158-ft length. It follows that, for preventing expansion of the remaining length, only 79 ft at each end of the long continuous welded rail need have the higher resisting and more expensive rigid type of track. Maintenance-of-way engineers contemplating the change to welded joints will be interested in verifying this conclusion. In this connection the writer wishes to make it clear that, although he recognizes the desirability of rigid track for the entire length of the rail, his present purpose is to emphasize and call attention to the basic fact that the longitudinal resistance is developed only as a reaction to movement, and this occurs near the ends of the rail, not at the middle, fixed part.

For rail laid in cold weather, it may even be necessary to provide lateral anchors, in addition to stiff track, to prevent the rail from buckling laterally and from being thrown out of alignment. On the other hand, for tangent rail laid in hot weather, with only the tensile stresses resulting from a drop in temperature, no special type of track may be necessary.

FORMULAS INCLUDING JOINT RESTRAINT

Fig. 3. shows the longitudinal resistance assumed to be increasing uniformly from the initial value, P, representing the joint restraint, to the maximum value, $F = E\ n\ \Delta t\ A$, that is required to fix the rail. As in the case without joint restraint, the change in length that is prevented depends directly on the stress developed in the rail, which is now:

$$s_x = \frac{P}{A} + \frac{T\,x}{c\,A} \qquad (12)$$

but as in Equation (4):

$$s_x = E\,\delta_x = E\,\frac{d\,(\Delta l_r)}{dx} \qquad (13)$$

Therefore,

$$\Delta l_r = \int_0^l \frac{1}{E}\left(\frac{P}{A} + \frac{T\,x}{c\,A}\right) dx \qquad (14)$$

and,

$$\Delta l_r = \frac{P\,l}{A\,E} + \frac{T\,l^2}{2\,c\,A\,E} \qquad (15)$$

The net expansion for rails shorter than twice the critical length, l'' $\left(\text{that is, } l < \frac{c\,(F - P)}{T}\right)$ is:

$$\Delta l = n\ \Delta t\ l - \frac{P\,l}{A\,E} - \frac{T\,l^2}{2\,c\,A\,E} \quad \text{................} (16)$$

FIG. 3.—FORCES IN A RAIL WITH RESTRAINED JOINTS.

Substituting the critical length,

$$l'' = \frac{c\,(E\,n\,\Delta t\,A - P)}{T} \quad \text{....................} (17)$$

required to finish fixing the rail, into Equation (16) will result in the simplified expression for maximum end movement with joint restraint, independent of the length, for any length of rail greater than the critical length (see Equation (9)):

$$\Delta l''_{\text{max.}} = \frac{c\,(E\,n\,\Delta t\,A - P)^2}{2\,T\,A\,E} = \frac{c\,(F - P)^2}{2\,T\,A\,E} \quad \text{...........} (18)$$

To Determine Values of P and T by Observation of End Expansions.— The procedure for determining the values of P and T by observing end expansions, is as follows:

(1) Measure Δl_1, the end movement with joint restraint from a fixed reference point, for a known rail temperature change from the laying temperature.

(2) Remove joint bolts, strike joint bars with a hammer to loosen their grip completely so that the ideal condition of free ends will be realized—to warrant applying Equation (9), which was derived with this assumption. Now, measure Δl_2, the end movement with free ends.

(3) Substitute Δl_2 and the temperature difference in Equation (9) (or Equation (18) which reduces to Equation (9) when $P = 0$) and solve for the correct tie resistance, T_2.

(4) Placing this correct value, T_2, and the first measured end movement, Δl_1, with the same temperature difference, in Equation (18), solve for the joint restraint, P; thus:

$$P = F - \sqrt{\frac{2\,(\Delta l_1)\,T_2\,A\,E}{c}} \quad \text{.................(19)}$$

Equation (19) can be simplified so that the ratio of the two measured end movements can be substituted directly in the formula to give the ratio of joint restraint to the total force required to fix the rail. Multiplying the term under the radical by $\frac{\Delta l_2}{\Delta l_2}$, or its equivalent, $\frac{\frac{E\,n^2\,(\Delta t)^2\,A\,c}{2\,T_2}}{\Delta l_2}$, from Equation (9),

$$P = F\left(1 - \sqrt{\frac{\Delta l_1}{\Delta l_2}}\right) \quad \text{...................(20)}$$

COMPARISON WITH OBSERVED EXPANSIONS

General.—For a comparison with general observed expansions in Germany, attention is called to the following quotations[6];

> "In Germany a 1 000′ length of rail moved ¼″ and ⅜″ at the joints. * * * The German engineers say the amount of movement at the ends regardless of the length is apparently only the normal movement for 40 ft. rails." [The movements for 100, 200, and 400-ft lengths were compared.]

In Australia, engineers of the Victorian Railways found that the actual expansion and contraction was about one-half the "theoretical" expansion. This was for rails as long as 250 ft, with standard track construction.

GRAPHICAL SOLUTION

Equation (9) can be transposed and written:

$$T = \frac{K\,(\Delta t)^2}{\Delta l'_{\text{max.}}} \quad \text{......................(21)}$$

in which,

$$K = \frac{E\,n^2\,A\,c}{2} \quad \text{......................(22)}$$

Example 2.—Equation (21) can be solved by reference to Fig. 4. For example, let the observed end movement, $\Delta l' = \frac{5}{16}$ in.; $\Delta t = 58°$ F; $E = 30 \times 10^6$; $n = 7 \times 10^{-6}$; $c = 22$ in.; $A = 12.86$ sq in. By Equation (22) the value of the track constant, K, is found to be 0.20. Then, entering Fig. 4 at $\Delta t = 58°$ F, intersect the curve, $K = 0.20$; proceed horizontally from the intersection to the radial line, $\Delta l' = \frac{5}{16}$ in., to determine the tie resistance, $T = 2\,100$ lb per tie.

---

[6] "Thermit Rail Welding," in a brochure pub. by The Metal and Thermit Corporation, New York, N. Y.

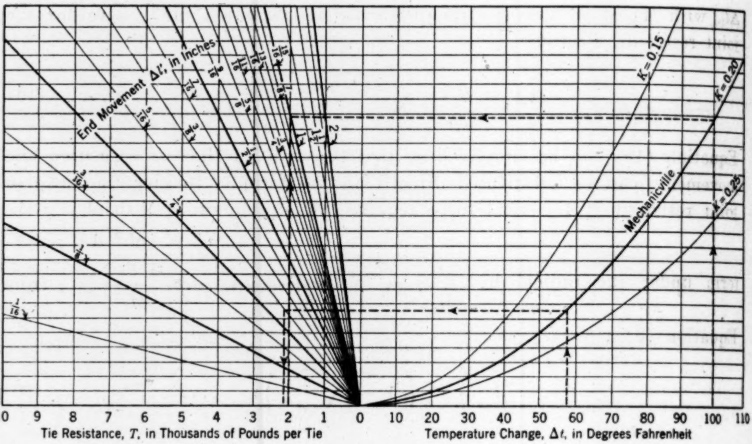

FIG. 4.—GRAPHICAL SOLUTION OF EQUATION (9).

Example 3.—Varying the conditions in Example 2, let $T = 2\,000$ lb per tie; $\Delta t = 100°$ F; and, $K = 0.20$. Proceed vertically from $\Delta t = 100$ to $K = 0.20$, as before; continue horizontally from this intersection to an intersection with the vertical line, $T = 2\,000$; and read the answer, $\Delta l' = 1$ in. on the diagonal lines.

APPLICATION OF THE FORMULAS TO THE MECHANICVILLE, N. Y., OBSERVATIONS

Example 4.—Four continuous half-mile lengths of welded A.R.E.A., 131-lb rail were laid in the main tracks of the Delaware and Hudson Railroad, at Mechanicville, on an extremely hot day, and the closing rail temperature was noted. Subsequently, the maximum observed contraction at one end was 0.75 in. for a temperature drop of 82° F. If the joint restraint were slight, or were removed entirely, Equation (9) (for free ends) applies.

The values of the track constants are: Cross-sectional area of rail, $A = 12.86$ sq in.; $E = 30 \times 10^6$; $n = 7 \times 10^{-6}$; and $c = 22$ in.

Substituting the observed values of $\Delta\, l_{\max.}$ and $\Delta\, t$ in Equation (9) (see heading "Graphical Solution") and neglecting the small tie movements gives a value for the average tie resistance to longitudinal movement of $T = 1\,860$ lb per tie. The average calculated value of T from forty observations (that is, both ends of four rails measured at five different times after installation) was 2 100 for an average movement of $\frac{5}{16}$ in., and an average temperature drop of 58° F.

Using a value of, say 2 000 for T, the maximum contraction for a temperature drop of 100° can now be predicted from Equation (9) (as shown in

Example 3), and results in the value, $\Delta l = 1$ in. This will be the same for any rail (with similar track constants) longer than twice the critical length, and from Equation (9) this length is: $L = 2\,l' = \dfrac{4\,\Delta\,l'_{\text{max.}}}{n\,\Delta t} = 475$ ft. Thus, the actual contraction is only one-half of what the free contraction would be at each end in a 475-ft length of rail, and one-eleventh of what it would be at each end in the 2 600-ft length.

Example 5.—With Joint Restraint.—Since it is quite likely that joint restraint did exist when the observations were made at Mechanicville, it is important to show how the additional data obtained in the suggested procedure for determining the degree of the joint restraint is to be applied in Equations (18) and (20).

Suppose after $\Delta\,l_1$ had been measured equal to 0.75 in., the joint bolts had been removed to allow the end to move freely an additional 0.50 in., making $\Delta\,l_2 = 1.25$ in. The correct value of the tie resistance can now be solved from Equation (9), or more directly by making use of the fact that the maximum end movement for free ends varies inversely as the tie resistance:

$$\frac{\Delta l_1}{\Delta l_2} = \frac{T_2}{T_1} \qquad (23)$$

or, $T_2 = \dfrac{\Delta l_1}{\Delta l_2}\,T_1 = \dfrac{0.75}{1.25} \times 1\,860 = 1\,120$ lb per tie. The number of ties required to develop the force, $F = E\ n\ \Delta t\ A = 222\,000$ lb, would be, for free ends: $N_2 = \dfrac{222\,000}{1\,120} = 198$ ties, and the critical length, $l' = 198 \times \dfrac{22}{12} = 364$ ft.

The number of ties and the length of rail that were originally in use, however, depended upon the degree of joint restraint. Applying Equation (20): $P = 222\,000\left(1 - \sqrt{\dfrac{0.75}{1.25}}\right) = 50\,000$ lb. The number of ties in use with this degree of restraint was: $N_1 = \dfrac{222\,000 - 50\,000}{1\,120} = 154$ ties; and, the critical length: $l'' = N_1\,c = 154 \times \dfrac{22}{12} = 282$ ft. This means that the maximum contraction (0.75 in.) would have remained the same at each end, for any length of welded rail from 564 ft to the actual length of the installation, 2 600 ft.

If the rail had been shorter than twice the critical length required to fix it completely, this fact would have been evident, according to Theorem 1, by its observed free end movement being greater than one-half the calculated free contraction. Equations (7) and (16) would then apply.

CONCLUSION

A complete analysis of the stresses in welded rail would have to include the complicated wheel load stresses in addition to the temperature stresses described in this paper. The various ways in which a rail can be stressed are summarized in Appendix II to show the extent of this subject and the necessity for limiting the present investigation to one particular aspect.

The principal objection to the introduction of continuous welded rail has been the fear of excessive expansion or contraction. The writer's purpose has been solely to answer this objection by presenting a theoretical explanation of the small observed expansions in existing long rails which are not accounted for under the existing "theory," thus establishing a sounder basis for future installations.

It is hoped that, with more observations of expansions, the correctness of the formulas presented in this paper will become established. It is only with this knowledge of what fundamentally takes place at the ends of the rail that the proper approach can be made to the economies resulting from the elimination of rail joints.

ACKNOWLEDGMENTS

The writer expresses his appreciation to his superior, F. W. Gardiner, M. Am. Soc. C. E., for making available the data suggesting the problem, and for the discussions which served as the basis for this paper. Credit is due G. M. Magee, Assistant Engineer, Kansas City Southern Railway Company, for his valuable help in checking the mathematical derivation of the formulas, and for his suggestions.

APPENDIX I

NOTATION

The following letter symbols have been adopted for use in the paper:

A = cross-sectional area of a rail, in square inches;
c = distance between ties; tie-spacing, in inches;
E = modulus of elasticity;
F = force; the total force required to restrain a rail, in pounds;
f = a subscript denoting free expansion;
H = modulus of horizontal resistance;
K = a track constant (see Equation (22));
L = total length of a rail or track;
l = length of a rail from one end to the middle, when the longitudinal resistance is insufficient to develop a force, F, to restrain a rail; Δl_f = change in length due to temperature change (in inches), with free expansion in the length, l; Δl_r = change in length that is resisted or prevented from taking place due to the cumulative effect of the tie resistance; l' = critical length, or length required to develop a restraining force of F lb, or a force sufficient to restrain the rail entirely; l'' = a critical length which includes the effect of joint restraint; Δl_1 = end movement when a joint is restrained, measured from a fixed reference point and corresponding to a known value of Δt; Δl_2 = end movement when a rail is permitted to expand freely;

N = number of ties required to develop the force, F;
n = coefficient of linear expansion, in inches per degree Fahrenheit per inch;
P = initial joint resistance to expansion, or contraction;
r = a subscript denoting "resisted," or "prevented";
s = unit stress;
T = resistance at the ends of each tie, in pounds; T_2 = correct tie resistance;
t = temperature of the rail, in degrees Fahrenheit; Δt = change in temperature from that existing when the rail was laid;
u = vertical modulus of foundation, in pounds per linear inch of rail per inch of vertical deflection;
δ = unit strain resulting from a stress, s.

APPENDIX II

Wheel Load Stresses

Wheel loads may contribute to the stresses in rails in the following ways:

1.—Static Stresses.—The rail is considered a loaded structure on a continuous elastic foundation. Under this assumption corroborated by field tests with extensometers, the stress, s_x, in the extreme fiber at a distance $\pm x$ from the position of the wheel load on the rail, is:

$$s_x = \frac{P}{4\,\beta\,Z}\,e^{-\beta x}\,(\cos\beta x - \sin\beta x) \dots\dots\dots\dots\dots (24)^{7}$$

in which P is the wheel load, in pounds; β is a symbol for conveniently representing the quantity, $\sqrt[4]{\frac{u}{4EI}}$; I and Z are, respectively, the moment of inertia and the section modulus of the rail about the horizontal neutral axis; u is the modulus of foundation; E is the modulus of elasticity for steel; and e is the base of the natural logarithms, or 2.718.

2.—Dynamic Stresses[8].—These are impact stresses caused by low spots in the rail, flat or out-of-round areas on the wheel, rail-joint gaps, differences in the elevation of adjoining rails, and vertical components of the connecting-rod and counterbalance forces in the case of steam locomotives.

3.—Shear Stresses.—Formulas developed by Thomas and Hoersch[9] give values for the high localized shear stresses that form slightly below the contact surface of the rail and wheel. Once the initial crack starts from this

cause, it spreads under the constant reversal of bending stresses of much smaller magnitude. Transverse fissures are examples of this type of overstress in the rail.

4.—Web, Fillet, and Bolt-Hole Stresses.—The sudden change of cross-section causes high concentration of stress which may result in minute initial cracks. These stresses can be calculated by photo-elastic methods.

5.—Torsion Stresses.—These stresses may be caused by eccentric vertical loads, and the lateral forces due to swaying, unbalanced centrifugal and superelevation forces, and flange pressures.

6.—Vibration Stresses.—Vertical and lateral oscillations of the truck and rail may produce momentary high stresses.

In addition to the specific references given in the footnotes, data on rail stresses may be found in the Progress Reports of the Special Committee on Stresses in Railroad Track published in the *Transactions* of the Society; the *Proceedings* of the American Railway Engineering Association; and the quarterly reports of the Rails Investigation being undertaken at the Engineering Experiment Station, University of Illinois, at Urbana, Ill.

DISCUSSION

CHESTER F. GAILOR,[10] ESQ. (by letter).—The calculations and the formula presented in this paper appear to be correct and should offer an excellent basis for continuing the study of this subject, as it is very evident that the information available heretofore is inadequate for modern track construction. The following factors entering into this subject should be taken into consideration in future studies and should be given adequate thought by engineers preparing to install rail in long continuous lengths:

(1) Most, if not all, of the rail laid in long lengths in the United States has been installed during the summer months when the expansion of the rail was greatest; therefore, the objections or complications from a practical point of view which might arise from this type of construction are vastly different from those that would arise if the same length of track was laid when the rails were shortest.

(2) Mr. Africano assumes that these long lengths of rail are laid in a perfectly straight line and that this alignment is so maintained. This is not exactly the case as can be ascertained easily and quickly by observing, with an instrument during a very hot day, the lateral variation in the alignment, to say nothing of the possible vertical movement that may occur in a similar manner.

(3) The free ends of long lengths of continuous rail will not expand any appreciable amount provided the rail is adequately fastened at each tie. This fact seems to have been clearly proved on the Delaware and Hudson installations.

(4) It would be well to emphasize the necessity of holding the rail definitely at each tie by means of a fastener that will always maintain a pre-determined gripping strength such as the spring fastenings exert on the rails laid on the Delaware and Hudson Railroad. The gripping strength required on this type of construction, is maintained at 1 500 to 2 500-lb pressure on the base of the rail by each spring fastener. It would appear that disastrous results might be expected if long lengths of rails were installed without similarly fastening the rails at each tie.

(5) The welding of long lengths of rails on electric railway systems has been in practice for many years and the question of expansion or contraction when rails are laid in paved streets is a subject which, to-day, requires only routine attention. However, the fact that the head of rails embedded in street pavement does expand and move laterally can be seen by observing, on a hot day, the effects of this action along the outside of the head of the rail, especially in asphalt pavements. This action is noticeable, even if the base of the rail is embedded firmly in concrete and, necessarily, not subject to such variations in temperature as are found in the head of the rail.[11]

---

[10] Cons. Engr., New York, N. Y.

[11] See *Proceedings*, Am. Transit Eng. Assoc. (formerly Elec. Ry. Eng. Assoc.), for information on this subject.

(6) The expansion or contraction of rails might well be better analyzed by assuming that fastenings at each tie are sufficient to hold all pressures or stresses that may develop between such fastenings. In practice, there is little or no evidence that these pressures or stresses are accumulative.

(7) There is need of more definite information on this subject, which should be obtained from a series of practical and laboratory tests, as the practice of laying long lengths of rail on railroad systems is rapidly becoming standard.

Mr. Africano should be commended for the thoroughness of his study and for the value of the information contained in his paper.

E. F. KENNEY,[12] ESQ. (by letter).—The vital feature in this subject of rail expansion is not so much the control of the linear expansion as the control of the lateral movement which might result unless very substantial fastenings are applied to the rail. It has been shown that some types of fastening are ample to take care of this feature, but it is not so certain that the fastenings used on the average railroad will do so safely. Thinking a little further, one wonders what would be the outcome when economic conditions affect the upkeep, even if fastenings are used which, when well maintained, are capable of holding the alignment.

C. W. BALDRIDGE,[13] ESQ. (by letter).—Under the title, "A New Theory of Rail Expansion", Mr. Africano gives a mathematical analysis of the forces resulting from expansion and contraction of steel rails in track, with a discussion of the probable performances of long rails or continuously welded rails. Tests of long rails have been attracting the attention of engineers since 1890 at least. The earliest tests, of which the writer has found record, consisted of an installation of 3 miles of rail on the Lynchburg and Durham Railroad, near Gladys Station, Va. A description of the test[14] shows the installation to have been made between March 19 and April 25, 1892. Three miles of 78-lb rail of the girder type, with the ends fitted tightly together, were jointed by having the bars riveted as tightly as possible. The track was then "buried in" with earth to the level of the top rail on the outside and to the level of the under side of the head on the inside of the track.

The report provoked considerable discussion, and established some values regarding the stresses resulting from such jointing of rails, which approach those calculated in later studies. Unfortunately, the promoter of the test claimed too much for the plan. He announced that continuous rail, buried in as it was in the test, would eliminate all need for track maintenance, and his attempt thus to handle the test resulted in the track getting into very bad condition. When the line was acquired by the Norfolk and Western Railway Company about three or four years after the installation of the test, the rails were removed and bolted-joint track was substituted for them.

[13] Asst. Engr., A. T. & S. F. Ry., Chicago, Ill.

[14] *Engineering News*, 1892, p. 388.

The history of the test seems to have ended with the publication of a reply by the Editor,[15] to a letter of inquiry regarding the test. In the reply, a list of the articles which had been published concerning the test was given.

Almost contemporary with the test on the Lynchburg and Durham Railroad was a test of long rails made on the Michigan Central Railroad, under the direction of A. Torrey, Chief Engineer of that line.[16] One section was composed of: One rail, 800 ft long; one rail, 500 ft long; two rails, 250 ft long, each; and two rails, 100 ft long, each. Originally, it was intended to construct these long rails by electrically welding 30-ft. lengths, but for a preliminary study Mr. Torrey constructed the rails by holding the individual 30-ft lengths together by means of the splices while the drilling for the turned bolts was done. The rail ends were not planes, but warped surfaces; consequently, the joints could not be held in intimate contact.

The rail was laid in the autumn of 1893 in a main-line freight track where the traffic was in one direction only, and consisted of all the east-bound freight business of the main line of the Michigan Central Railroad. The speed over this track at that time did not exceed 20 miles per hr, but brakes were often set and engines sometimes reversed, as it was in the vicinity of an interlocker.

The points to be determined by the tests were (quoting Mr. Torrey):

> "(1) Whether a long rail would move freely enough on ties to be safe under sudden and extreme changes of temperature;
>
> "(2) What provisions would have to be made to hold a long rail from creeping under traffic in one direction only;
>
> "(3) Having been forced to use rails held in abuttal instead of welded, whether the joint would be stiffer with the rail ends in abuttal than the ordinary joint is;
>
> "(4) Whether the life of the rail would be appreciably greater if the opening between the heads of the rails was eliminated and the splice relieved from the wear occasioned by the movements of the rail due to temperature changes."

Referring to Item (2), it was reported that under the speed of such traffic as this track accommodated, the rails did not drag the ties, since they were securely connected to other ties for a distance of 28 ft at the point of fastening. The answer to Item (3) was found in the result of tests made at the University of Michigan, Ann Arbor, Mich., which began with the assumption that the stiffness of the full rail was 1. The stiffness of the joint with abutted rail ends was $\frac{1}{2}$, and the stiffness of the joint with $\frac{1}{8}$-in. expansion and without the turned bolts was $\frac{1}{3}$, comparatively. The tests were made with the rails upright and inverted, and the proportionate stiffness was the same for each position.

From December 26, 1893, to January 20, 1894, measurements of the movement at the expansion joints were made in the morning. From January 20 to mid-summer, measurements were made at 7:00 A. M., on

---

[15] *Engineering News*, March 22, 1906.

[16] *Railroad Gazette*, July 27, 1894, p. 518.

Sundays, and at 7:00 A. M., and at noon, on week days. From December 26, 1893, until April 14, 1894, the theoretically proper range of movement was based on temperatures obtained from the United States Signal Office. From April 15 to mid-summer, the theoretically proper range of movement was based on temperatures obtained from a thermometer embedded in a piece of rail alongside the long rail. In the colder months the rail movement was considerably less than would be forecast from the changes of temperature during those months, if such forecast should be made in the light of the sensitiveness of the rail to changes of temperature, as shown between May 17 and May 20. Mr. Torrey concluded that the rail may or may not assume the air temperatures when the ground is frozen and stated finally that: "* * * defects of construction entered into it [the rail], which would naturally be discarded in its successor, if it has one, and the results as to smooth and noiseless passage of the wheels would probably be more favorable under better conditions."

Another study of longer rails was made public in a committee report on the subject, "Miter Cut Ends and Longer Rails," which was presented at the Convention of the Roadmasters and Maintenance of Way Association of America in the autumn of 1895, in which some comments of interest are to be found.

In recent years interest in the subject of the use of continuous, or very long sections of rail welded together, has resulted in actual tests being made on the Delaware and Hudson Railroad, in four different locations and under somewhat different conditions. Another installation of rails welded together for a full mile has been made on the Bessemer and Lake Erie Railway. These tests are making history and are attracting the attention which such studies deserve.

Although actual tests of continuous rails are necessary to prove conclusively whether or not such installations are dependable and practicable, some information regarding actions which result from contraction and expansion of long rails may be gleaned from the results of the shearing off of track-bolts in rail-joints during periods of severe cold weather.

In 1924, the writer had occasion to investigate a case in which, on a severely cold night following a mild day, nineteen joints in a distance of about 25 miles had sheared off both bolts in one end of the joint, thus allowing the rails to pull apart. The track was laid with 90-lb rail, all-steel joint bars and oil-quenched bolts. Inquiry as to maintenance revealed the fact that the joints had been bolted up as tightly as possible, using wrenches which, by means of pieces of pipe, had been lengthened from 46 to 48 in. The bolt-tightening had been done during an unusually warm spell late in the autumn. A few weeks later a sudden drop in temperature to − 18° F resulted in the shearing of the bolts at joints where for some reason the bolts were less tightly set, thus permitting the rails to slip through the joint bars. Notwithstanding the fact that the track was equipped with single-shouldered tie-plates and only four cut spikes per tie (two for each rail), none of the openings between rail ends widened to more than 5.5 in.

During the present winter (1936–37) a number of joints in track laid with 112-lb, all-steel joints, and high carbon, oil-quenched bolts, have sheared two bolts, allowing the rails to pull apart as far as the contraction would take them. In these cases, the track is also equipped with single-shouldered tie-plates and with four cut spikes per tie. The bolts had been installed by bolting machines when the rail was laid, followed by normal maintenance. Most of the adjacent joints showed that no movement had occurred through the bars, and in most cases the sheared bolts occurred in joints a mile of more apart; yet in these cases the opening between the rail ends was usually about 2 in. and none was reported to have opened more than 2.5 in., even when temperature readings below zero were experienced. These rails were laid using expansion shims based on rails that were tight at 100 degrees.

Taking the coefficient of expansion at 0.0000065 (which is the value generally used for railway rails), the width of opening found in these cases represents the contraction of only 320 ft of rail, and assuming that it was equally effective in both directions, it shows that the contraction of rail steel, due to zero temperature, is overcome by the resistance to movement of only 160 ft of 112-lb rail held by cut spikes in a normal manner.

In order to determine the results, of the forces created by the expansion and contraction of steel due to temperature changes, it is pertinent to begin with a single rail and then to build up a series of rails. It is easy to recognize that a single rail, 39 ft long, resting freely with no connections except the support under it, will have no movement, as a whole, due to contraction and expansion. Connect two rails of the same size, weight, and length, and each rail will exert the same pull upon the other. Add a third rail and the pull of Rail No. 1 upon Rail No. 2 will be equal and opposite to the pull of Rail No. 3, and since the resultant of equal and opposite forces is zero, there will be no movement. It becomes evident, therefore, that as long as there is no break in the connecting joints in a track the forces of expansion or of contraction nullify each other and there is no resultant force to produce movement. It is also evident that if the rails in a track are rigidly connected, the forces acting nullify each other, except for the short distance at each end where the resistance to movement produced by the weight of the rail and the grip of the spikes is less than the unbalanced force of contraction or expansion.

The widths of opening between rail ends, resulting from the shearing of bolts prove that such distances are not great and also that they are shorter for heavy rails than for lighter ones.

These actual results in track go far to confirm the accuracy of the mathematical determination of forces resulting from, and the resistances to movement due to, contraction or expansion of long rails, as given in Mr. Africano's paper. The results found in track as described herein, with the studies made by Mr. Africano, by the Kansas City Southern Railroad Company, by the Rail Committee,[17] and the Track Committee,[18] of the American Railway Engineering Association, and by others, give favorable indication of the practicability of the use of continuously welded rails.

---

[17] *Bulletin No. 391*, A. R. E. A., November, 1936, p. 233.

[18] *Bulletin No. 393*, A. R. E. A., January, 1937, p. 493.

George W. Hunt,[19] Esq. (by letter).—First considering the condition of a rail perfectly free to expand, Mr. Africano proceeds to the condition in which the ends are restrained by means of ballast resistance to tie movement, and, finally, to the condition in which the ends are restrained partly by the ballast resistance and partly by the joints connecting the welded section with the adjacent track sections. The equations developed by Mr. Africano are applicable to all lengths of welded track, from a few rail lengths to a number of miles. Their purpose is to show the relation between: (1) Tie resistance; (2) joint resistance; (3) rail movement under various changes in temperature; and (4) to indicate the proper balance between these factors in order to avoid damaging strains and stresses after the rail is welded.

As Equation (18) contains all of the aforementioned factors ((1) to (4)), and represents the third condition, it may be accepted as the general equation. Equation (9) is simply a special case of Equation (18) when the joint restraint, P, is reduced to zero. For analytical purposes, P may be expressed in fractional parts of F, the total force required to restrain the rail, and incorporated in Fig. 4, thus making this graph to include all factors in the problem. For example, Equations (21) and (22) which determine the values of T for the case of no joint restraint, can be restated as follows to take joint restraint into account:

$$T = \frac{K' (\Delta t)^2}{\Delta l''_{\max}} \qquad \text{(25)}$$

in which K' (see Equation (22)) equals $0.5\,K$ when $P = 0.3\,F$; $0.25\,K$ when $P = 0.5\,F$; and $0.0625\,K$ when $P = 0.25\,F$; and $F = 2\,816\,(\Delta t)$. In Fig. 5, the value of T can be read for various degrees of tie restraint. For example, suppose that $P = 0.3\,F$; then, for 130-lb rail, with a temperature change of 100°, $P = 0.3 \times 281\,600$ lb $= 84\,400$ lb. For a 60° temperature change, $P = 0.3 \times 2\,816 \times 60 = 50\,688$ lb. For these two temperature changes Fig. 5 shows that $(\Delta l'')_{max}$ (the rail end movement) has the values shown in Table 3.

TABLE 3.—Values of $(\Delta l'')_{\max}$

Values of tie restraint, T, in pounds	Critical Length, $(\Delta l'')_{\max}$, in Inches, for Temperature Changes of:	
	100° F	60° F
750	$1\frac{3}{8}$	$\frac{1}{2}$
1 000	1	$\frac{3}{8}$
1 250	$\frac{11}{16}$	$\frac{1}{16}$

It is the opinion of the writer that the influence of joint restraint has been under-estimated in the test at Mechanicville, and that if the facts were known the joints at the free ends (so-called) were furnishing part of the resistance, and that the ties were furnishing considerably less than 2 000 lb. The opinion is based on his understanding that the joint gaps at the "free" ends were as much as $\frac{7}{8}$ in., at the temperature drops mentioned in this test.

---

[19] Maintenance Inspec., M. of W. Dept., Baltimore & Ohio R. R., Baltimore, Md.

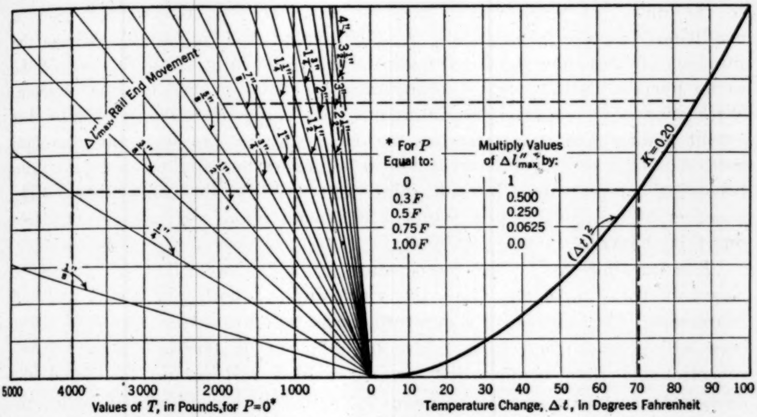

FIG. 5.—RELATION BETWEEN RESISTANCE, TEMPERATURE CHANGE, AND RAIL MOVEMENT UNDER VARIOUS DEGREES OF JOINT RESTRAINT.

Joint restraint in tension is composed of the frictional resistance between bars and rail, plus the bending resistance of the bolts. The frictional resistance in a 6-bolt joint may be taken as $(3 \times 20\,000 \times 2) \div 2 = 60\,000$ lb. The bending resistance of one bolt may be taken as 8 000 lb, or 24 000 lb for three bolts. On this basis the total joint resistance would amount to 84 000 lb, or about 30% of the force, F, required to restrain a 131-lb rail under a temperature drop of 100 degrees. It seems reasonable, therefore, to consider the ultimate value of P in tension as equal to $0.3\,F$. In this connection, it should be remembered that the rail-drilling, bar-punching, and bolt diameter for 131-lb and 112-lb rail sections are proportioned so as to allow only a $\frac{3}{8}$-in. rail gap before bringing the bolts into bending resistance. It follows, therefore, that when the joint gaps exceed $\frac{3}{8}$ in., the frictional resistance of the bars against the rail has been overcome and the bolts are exerting bending resistance. In compression, the ends of the rails come into contact before any bending strain is thrown on the bolts, so that the joint restraint in compression may be taken as 60 000 lb. The fact that a joint gap has greater latitude to enlarge under tension than to contract under compression is one reason why welded track should be laid or closed at temperatures that favor tensile strains, rather than compressive strains. The major reason is that the track is less likely to be thrown out of line by contraction in cold weather than by expansion in hot weather.

Mr. Africano conceives joint resistance as that force at which the joints in the adjacent unwelded section will begin to yield and continue to yield, sufficiently to accommodate $(\Delta l'')_{max}$, the rail-end movement. The actual value of the joint resistance is of little practical importance, serving only to explain the variation in the value of $(\Delta l'')_{max}$ as between theory and practice. In no case could it exceed the value of F; to do so the unwelded track would have to be as stiff as the welded track, a condition scarcely attainable. A high value for it would reduce the number of ties necessary to restrain the rail fully, but this would be to no purpose as long as a special track construction was used throughout. With increasing values it would reduce the value of $(\Delta l'')_{max}$ and to that extent reduce the movement at the rail gaps in the adjacent unwelded section. This objective is desirable as a precaution against tensile strains becoming concentrated in one joint and pulling the rails apart. The question of using expansion joints will depend upon what weight is placed on this hazard.

The question as to the temperature at which welded track should be closed is very important from the viewpoints of both rail stress and rail movement. A range of temperature from 20° below zero to 130° above zero will give a mean temperature of 55°; but as tensile strains are less objectionable than compressive strains, welded rail should be closed and anchored at a temperature between 70° F to 80° F. If this is done, the temperature change above the closing temperature need not exceed 60° and the rail movement in compression will be limited to that temperature change. Similarly, the temperature change below the closing temperature will be limited to 100° and the rail movement in tension to that temperature change.

The value for tie resistance, T, as applied to fairly well ballasted track, has probably been over-estimated in much of the discussion on this subject. There is a temptation to place too high a value on this factor, for rail laid at high temperature, on the theory that with a severe drop in temperature below the closing temperature, the ballast will freeze and thus increase the tie resistance, restrict the contraction movement, and build up the value for F in a shorter distance. This reasoning appears fallacious when it is considered that the rail responds very quickly to temperature change; freezing is a slower process and could scarcely occur in time to offer any resistance to rail movement. In fact, in the absence of sufficient moisture, the ballast may not freeze at all; it may have no higher resistance in cold weather than in warm weather. If the ballast did finally freeze, subsequent to the rail movement, and a thaw should set in, the temperature would have to rise to the closing temperature before any reversal of tie restraint could occur, and considerably above this temperature before the reversal of tie restraint reached any great magnitude. By this time the thaw, in all probability, would have begun to loosen up the ballast. It is felt, therefore, that the process of freezing and thawing can be disregarded as far as influencing the ballast resistance, and that the factor, T, can be accepted as a fairly constant value for any given ballast section, throughout the year.

An approximation of this value can be made for loose ballast by taking one-half the weight of the rail, ties, and ballast, above the bottom of the ties for a distance of 22 in., and multiplying it by the coefficient of sliding friction, taken as unity. For loose ballast, $T = 0.5\ (192 + 175 + 755) = 561$ lb; and, for packed ballast, with the usual degree of cementation, it would seem that 1 000 lb per tie per rail, is all that could be depended on. Table 4 is illustrative of the manner in which $(\Delta l'')_{\max}$, the rail end movement, varies with variation in temperature change, when $T = 1000$ lb and $P = 0.3\ F$. Items Nos. (3) and (4), Table 4, represent the conditions that are said to have existed at Mechanicville, so far as temperature change and rail end movement are concerned. The division of restraint as between ties and joints are the results of the writer's construction and about this there may be a difference of opinion.

TABLE 4.—VARIATIONS IN $(\Delta l'')_{\max}$

Item No.	Tie restraint, T, in pounds (1)	Changes in temperature, Δt, in degrees Fahrenheit (2)	Restraining force, F, in pounds (3)	Joint restraint ($P = 0.3\ F$), in pounds (4)	Number of ties, N, required to develop force, F (5)	Critical length, l'', in feet (6)	Critical end movement, $(\Delta l'')_{\max}$ in inches (7)
(1)......	1 000	100	281 600	Free end	432	792	2
(2)......	1 000	100	281 600	84 480	197	361	1
(3)......	1 000	82	230 910	69 270	162	297	$\frac{11}{16}$
(4)......	1 000	58	163 330	49 000	114	209	$\frac{5}{16}$

Where the welded track is isolated (that is connected at both ends by unwelded rail with the usual joints), these rail end movements, even in the case of Item No. (2) are not alarming. They would not result in any greatly enlarged rail gap, as in all three cases, the value of P is sufficient to distribute this movement through from two to four joints. Insulated joints, however, would present a problem, particularly in Item No. (2). Required to withstand a tensile force of 281 600 lb they would be able to withstand only 84 480 lb, and a rail gap of 2 in. would result if the joint failed. The only recourse, as a matter of precaution, would be to install several ordinary rails on either side of the insulated joint so that this movement could be distributed through several joints, or to adopt some extraordinary means of increasing the joint resistance. A similar problem will be encountered at all switch-point joints, on the frog side as well as at the heel joints of all frogs. Here Condition No. (1), Table 4, would obtain, due to the break in the continuity of the main-track rail by the switch-point, and the 2-in. rail end movement would have to be provided for either by a single expansion joint, or by the more simple expedient of installing about four or five rails with ordinary joints, in advance of the switch-point and heel, to distribute this movement. For obvious reasons, both economical and practical, welding through yards involving main-track turnouts should be avoided, and the welding should be terminated at the entering and leaving turnouts to yards.

Item No. (1), Table 4, shows that $(\Delta l'')_{\max}$ amounts to 2 in. when the joint resistant is zero. It follows, therefore, that if a rail broke at a temperature drop of 100°, there would be a rail gap of 4 in. If no special track construction was used to utilize the tie resistance, the rail gap would be 8 in. This is one reason why it is advisable to bind the rail to the ties throughout, rather than just for a distance, l'', sufficient to develop the force, F.

It is apparent that if a rail broke, or if for any reason a section of rail were removed, it should be replaced by one of identical length, otherwise abnormal rail stress or rail end movement may result when the temperature changes radically in the other direction. The repair of a broken rail at a radical temperature change without restoring the rail gap, has the effect of creating a free-end condition at the break at that temperature as regards rail strain, without providing any means for rail movement when that temperature alters radically. What would happen under a radical change in temperature in the opposite direction is best illustrated by studying some specific case, such as that of a welded track laid at 80° F. A rail breaks at zero temperature, leaving a gap at the break of $2\frac{3}{4}$ in., and is repaired by cutting out a distance sufficient to accommodate a new 39-ft rail and then re-welding. The temperature subsequently rises to 130° F. How will the rail stress and rail end movements at 130° compare with these same factors if the rail had gone through temperature changes and not broken? What happens can be best illustrated by reference to Fig. 6, which shows that, had the rail not broken, the rise in temperature to 130° would have resulted in a unit compressive stress of only (140 800) ÷ 12.86 = 11 000 lb and the rail end movement would have been $\frac{3}{16}$ in.

FIG. 6.

The breaking of the rail at 0° F and its repair by adding 4 in. to the length would result in a concentrated compressive stress at the break of 366 080 ÷ 12.86 = 28 500 lb when the temperature rises to 130° F. This stress would hold as long as the break was far enough away from

End *A* for the ties and joint restraint to develop a force of 366 080 lb. In Fig. 6 this distance is 148 + 414 = 562 ft. Fig. 7 shows the conditions that would exist had the rail broken 300 ft from the end of the welded section. The theoretical gap at the break would be $1\frac{7}{8}$ in. at zero temperature which it may be assumed, was not restored when repaired. When the temperature rises, a movement of the rail end will occur equal to $1\frac{7}{8} + \Delta l''$.

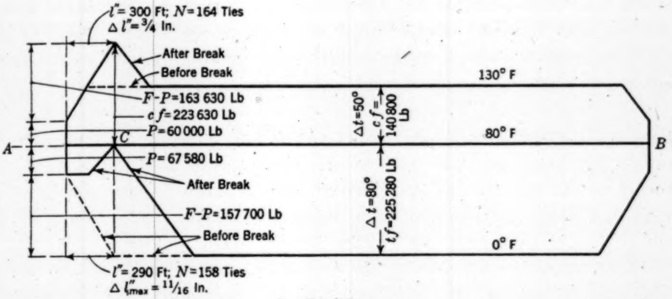

FIG. 7.

When a temperature of 130° is reached, a peak of maximum value for *F* will arise at Point *C*, Fig. 7, determined by the value of the joint resistance plus the tie resistance developed in 300 in. This value will be $60\,000 + (300 \times 12 \times 1\,000) \div 22 = 223\,630$ lb, or equivalent to a maximum unit stress of 18 400 lb per sq in. The rail movement at 130° will be equal to $1\frac{7}{8} + \Delta l''$. From Equation (18) the value for $\Delta l''$ is $\frac{3}{4}$ in., and the total rail end movement will be $2\frac{5}{8}$ in.

Should the break occur at or very close to End *A*, where the only force is the joint restraint, the rails would separate very little if they broke. Even if they separated considerably, the neglect of correction would have no effect on the stress in the welded section. The sole effect of this neglect would be to limit the room for expansion at higher temperatures, in the joints of the adjacent unwelded track.

This discussion shows that the repair of broken rails without restoring the original strained condition, may result in one of two conditions: Either the stress may be radically increased locally, adding to the hazard of buckling track, or the end movement may be increased radically, creating a necessity for expansion joints. Repairs in cold weather would create excessive compressive strains in hot weather, and repairs in hot weather would be likely to create excessive tensile strains in cold weather. It follows, therefore, that welded rail should be repaired wherever possible at or close to the temperature it was laid, and that any work of this kind will require the most rigid rules and careful supervision.

Although rail welded into continuous stretches should reduce greatly the necessity for lining and surfacing track, all such work would have to be done with the utmost care. "Out of face work," such as raising track, cleaning cribs, and re-ballasting, should not be undertaken except at temperatures bordering on that at which the rail was laid, say, between 55° F and 95° F. ("Out of face" is a term used by track forces; it denotes a fairly long piece of track as distinguished from the one or two rail lengths. "Out-of-face surfacing," means the raising and tamping of all joints continuously; "spot surfacing" means just raising a joint here and there.)

With due consideration to the features mentioned, the writer can see no reason why welding of rail into continuous stretches cannot be practiced with perfect safety, with resulting economy, and greatly improved riding conditions.

FRANK B. WALKER,[20] M. AM. SOC. C. E. (by letter).—The mathematical formulas developed by the author are of interest to maintenance-of-way engineers, and the conclusions derived are apparently confirmed, at least in part, by the experience of the Eastern Massachusetts Street Railway Company in maintaining 210 miles of unpaved, welded track. At one time, there were 150 000 welded joints on that street railway.

The major part of the welding on this track was done from 1919 to 1923, but the change from trolley cars to buses during recent years has caused the abandonment and removal of most of it. The rail sections welded were 48-lb, 60-lb, and 75-lb tee-rail (Am. Soc. C. E. standard). The standard track consisted of 6-in. by 8-in. by 8-ft wooden ties, spaced 2 ft on centers; $5\frac{1}{2}$-in. by $\frac{9}{16}$-in. track spikes; and 6 in. to 12 in. of gravel ballast. There were no tie-plates. The rail welded in 1919, 1920, and 1921, had few expansion joints although some of the sections were more than a mile in length, as indicated in the following list:

Location	Feet of track welded
Brockton and Easton	15 600
Boston-Randolph	10 000
Brockton, Crescent Street	6 300
Salem-Danvers Line	8 300
Danvers-Danvers Center Line	6 400
Peabody-Danvers Line	11 600

No serious difficulties due to expansion or contraction were encountered in maintaining such long sections of welded track. Occasionally, during a very cold winter night, especially when the temperature was falling rapidly to near zero, a rail would break. Rail defects, together with high tension due to temperature changes, were believed to have been the cause, as they occurred only in old rail. New rail did not break under these conditions. It may be assumed that the difference in temperature from the time of welding to the time of failure was from 70° F to 100° F. Only one or two of the so-called "sun kinks" occurred during hot weather (see Fig. 8).

---

[20] Cons. Engr., Eastern Massachusetts Street Ry., Boston, Mass.

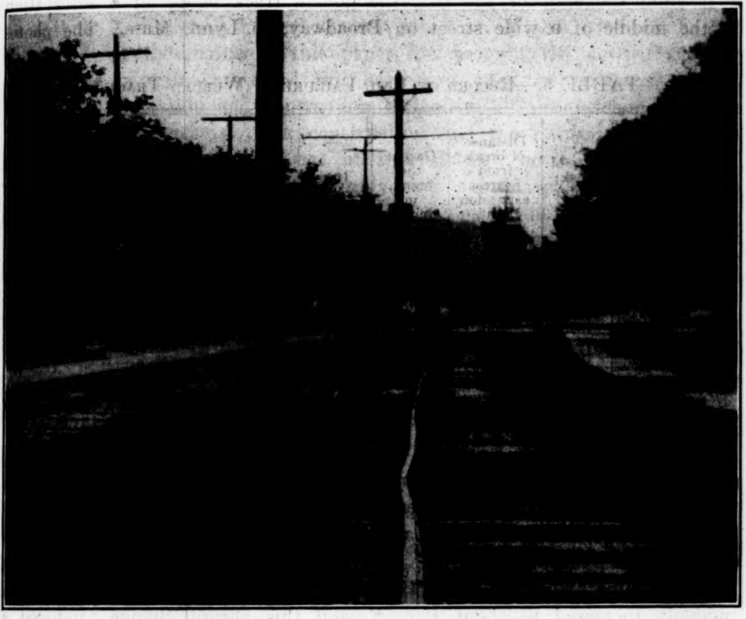

FIG. 8.—VIEW OF A "SUN-KINK" ON A WELDED TRACK.

When the rail broke, or when a sun kink appeared, expansion joints were installed (not necessarily at the break), about 20 rail lengths or 600 ft apart on tangents and at the ends of long curves. After the installation of expansion joints no sun kinks occurred, but rail breaks on old rail did occur occasionally. Sometimes these breaks were at long distances from the expansion joints, and at other times only a few feet, or a rail length, away. Where expansion joints were 660 ft apart, it was thought at first that the expansion would be 6 in.; but it was soon learned that the actual expansion did not exceed one-half the anticipated expansion. This phenomenon is mentioned by the author in connection with the experience on the Victorian Railways in Australia.

Hundreds of expansion joints were examined during hot and cold weather over a period extending from 1922 to 1934, and their movement, due to temperature changes only, did not exceed the 2 to 3 in. When a rail broke, it gave a very loud report and the ends separated by a distance never in excess of 2 in. Table 5 contains information concerning thirteen broken rails, the distance of the break from the nearest expansion joint, and the gap at the break.

The rail in Fig. 8 was a 60-lb tee-rail (Am. Soc. C. E. standard), laid on chestnut ties, 2 ft apart, without tie-plates, with $5\frac{1}{2}$-in. by $\frac{9}{16}$-in. track spikes, and about 12 in. of gravel ballast. There was a stone curb about 2 ft from the ends of the ties, the double track being in a reservation in the middle of a wide street on Broadway, in Lynn, Mass. The photograph (Fig. 8) was taken a few minutes after the sun kink appeared. The rail was welded in the summer of 1920. It was in service through the remainder of that summer, an unusually cold winter, and a late, cold spring

* In each case the atmospheric temperature was reported as "falling"; and, each expansion joint was oiled.

† Break adjacent to joint.

Some time in early June, 1921, after a cold night, the temperature suddenly increased to about 100° F, and this abrupt change produced a sun kink, in one track only. The kinking of the rails also moved the ties laterally. There was no noticeable bending or displacement of the track spikes. It is believed by the Company Engineers that this sun kink would have occurred even if a more substantial type of rail-fastening, such as larger or more track spikes, screw spikes, or even shoulder tie-plates, had been used. As far as had been observed previously the rail had been in perfect line and surface. There were no expansion joints at the time the sun kink occurred, but expansion joints were installed immediately and no further trouble occurred. The track was discontinued in 1935.

Another kind of difficulty occurred on a hot summer day when a man's leg was almost cut off when he pulled out too many spikes in renewing ties. The rail popped out of the remaining spikes, catching his leg against the adjacent rail.

It is obvious from the author's mathematical discussion and from the testimony of those experienced with maintaining welded track, that ballast must be of sufficient width, depth, and character to withstand the thrusts put upon it during hot weather; and no doubt the construction with tie-plates, and with better means of fastening rail than by ordinary track spikes, is desirable. The rail will withstand, safely, the additional tension induced by a decrease in temperature. It is suggested that no welding be done when the temperature is extremely hot or cold.

Arthur N. Talbot,[21] **Past-President and Hon. M. Am. Soc. C. E.** (by letter).—To many engineers, this paper has brought the news that long stretches of continuous welded rail have been used on railroads without troublesome expansion and contraction difficulties. To those familiar with modern developments in track construction and the nature of the forces applied to the track it was not unexpected that, on a long stretch of continuous welded rail connected firmly to a suitable substructure of ties and ballast, the cumulative anchorage of the ties in the ballast at the two ends will reach a total force sufficient to hold an intermediate section stationary and fixed through the usual range of atmospheric temperature without changes in length, except for local effects. In the substructure used in present installations the rail is secured firmly to each tie in a manner such as to prevent slippage between rail and tie either longitudinally or transversely of track, and the ties are well bedded in ballast. This anchorage must be such as to provide adequately for the great force required to hold the intermediate section in a fixed position during temperature changes equal to those obtained in both summer and winter exposure and also to provide adequate transverse support against lateral buckling during the highest temperatures. These requirements imply a construction differing from the ordinary run of common track, in which the rail can be lifted from the tie a short distance and is held by anchors along its length only roughly and not fixedly with respect to the ties; that is, the rail must be fastened to the tie so that there will be neither longitudinal nor transverse movement between them, and the relation between tie and ballast bed must be one of firmness and security.

It is obvious that an analysis of the action of welded rail under such conditions must be based on known or assumed premises and, as in all reasoning, the validity of the analysis will be contingent on the validity of the premises. A start must be made to learn what underlying bases to use.

In beginning an analysis in this matter, one naturally first makes inquiry as to the possible ways in which the end portions of the track may act. Many questions arise. In developing the anchorage that will fix the unmoving intermediate part of the length of the welded stretch, does the anchorage act elastically? Does the anchoring force push the ties and ballast longitudinally along the track with the changes in temperature, even in small amounts? Is the nature and magnitude of the resistance the same in backward and forward directions—that is, with rising and falling temperatures? Do the ties near the end of the welded stretch, where the movement of the rail under temperature changes is greatest, give a greater resistance (greater rate of anchorage) than the ties at points farther from the end but within the moving length; or does the anchorage resistance have the same value (rate) all along this end portion; or does some other law govern?

---

[21] Prof. Emeritus, Coll. of Eng., Univ. of Illinois; and Chairman, Committee on Stresses in Railroad Track, Urbana, Ill.

Whether or not the tie-and-ballast rate of anchorage is uniform along the length of the anchorage stretch, does the magnitude of the length of the anchoring portion vary with the magnitude of the change in temperature of the rail, or is it constant throughout any range of temperature? In other words if the rise in temperature from the laying and fastening temperature is at first 40° and then 40° more, does the 80° increase in temperature result in twice as long an anchorage length as the 40° increase?

Then, there are questions as to the source of the anchorage. Granting that the rail does not slip over the tie (considered as essential in this form of construction) is the anchorage due to friction of the ties on the ballast by reason of pressure of the tie on, and in, the ballast so that the anchorage rate will have a constant value throughout any given anchoring stretch; or does the anchorage utilize some compressive resistance in the ballast, ties, and fittings? If the latter, does the movement of the tie within the ballast bed vary with the longitudinal anchorage force developed? How can the rail at the end of the stretch move without a movement of the ballast? For sensible movements of the rail end, will the tie move sufficiently to leave a crack behind it which would be closed on reversing the temperature change? Furthermore, if the ultimate resistance is reached, what will be the nature of the failure (all materials have their ultimate resistance)? Will it shear along a plane under the ties, or what?

These queries and others, although important, must mostly await further experience and investigation. Without definite and explicit information concerning some of them it is natural that in starting an analysis the easiest and simplest assumptions would be chosen first. The simplest and most probable assumptions to use would seem to be that for a given track: (1) The anchorage rate is uniform in magnitude over the length of the end portion that acts as anchorage restraint; and (2) the value of the rate of anchorage force is constant regardless of the magnitude of the change in temperature from the laying temperature of the welded rail.

These two assumptions are made by Mr. Africano, at least implicitly. They were chosen tentatively by the writer when, in 1935, he began considering the phenomena of long stretches of welded track preliminary to planning tests and observations on the track of the Delaware and Hudson Corporation for the Track Stresses Investigation of the Joint Committee on Stresses in Railroad Track, which is a co-operative investigation of the Society and the American Railway Engineering Association. The assumptions formulated at the time with other statements of the accompanying conditions in part were as follows:

> "To study the general action of the track in a preliminary manner, use may be made of assumed anchorage conditions. The simplest one and the one most likely to come to mind is the assumption that each tie toward the ends contributes the same increment of force and these many increments

together accumulate a force of sufficient magnitude to restrain and anchor the intermediate portion of the rail fully so that it will not contract or expand under the given change in temperature. A second simple assumption may be made, which at first thought may be considered a corollary of the first one although it is not, that the magnitude of the restraining force developed at a tie along the two anchoring stretches of the long rail has a constant value regardless of the magnitude of the temperature change. The validity of these two assumptions can be tested from observations on the action of the track. At any rate they will be useful in discussing the possible magnitude and distribution of the anchorage forces and the movement of the end portions under temperature change."

In the study, the calculus method was first used similar to the method given in the paper, but the premises assumed were so simple that it seemed sufficient and preferable to use the analogy of constant increments of force and of constant acceleration, following the laws of mechanics, and at once write the equations for length of anchorage and for rail movement without the more formal phraseology of the calculus. The force transmitted through the joint at the end of the stretch was included readily in the general consideration. It should be stated that this discussion refers to stretches with a length more than sufficient to give full anchorage. Some of the further statements formulated at that time (omitting the derivations and using the notation of the paper under discussion) were:

"(1) The anchorage force required to restrain the intermediate portions of the length of rail so that it will not change its length with a change in temperature is:

$$F = \Delta t\, n\, E\, A \qquad (26)$$

this force being independent of the length of the fully restrained part and the unit stress there being $s = \Delta t\, n\, E$. (See Equation (2).)

"(2) Calling l'' the length of the end part of the rail (that giving the anchorage to the intermediate and fully restrained portion), under the assumption of a uniformly increasing stress in the rail from zero at the end of the rail to the full stress, s, at the other end of the anchorage and, likewise, to the full anchorage force, $\Delta t\, n\, E\, A$, the movement of the end of the rail will be one-half the full temperature expansion or contraction for the length, l''; that is, $0.5\, \Delta t\, n\, l''$. Likewise, the distribution of the anchorage force along l'' will be per unit of length,

$$\frac{F}{l''} = \frac{\Delta t\, n\, E\, A}{l''} \qquad (27)$$

Likewise, the length of the anchorage under the assumption made, is:

$$l'' = \frac{\Delta t\, n\, E\, A}{q} \qquad (28)$$

Even with the assumptions used further information will be needed.

"(3) From Assumptions (1) and (2) and Equations (26), (27), and (28), certain deductions may be made: (*a*) Assumption (2) implies that for any given change in temperature the full available anchorage force per unit of length (and likewise the anchorage force per tie) will be developed and applied on the anchorage portion, whether the temperature change is small or large; and by Assumption (1) this same maximum available anchorage force per tie is applied uniformly along the anchorage portion; (*b*) the length of the anchorage portion with a given available anchorage unit per length or per tie will vary directly as the temperature change—twice as great a temperature change will require or use twice as long an anchorage length; and (*c*) the movement of the rail end for the same conditions will vary as the square of the temperature change—twice as great a temperature change will result in four times as great a movement at the rail end."

Naturally, the observational tests on welded track of the Stresses in Track Investigation were planned to cover the validity of the two assumptions. As the results of the tests are giving needed cumulative information as to the action of welded track, it seems germane to the discussion of this paper to present some of the results which bear on the assumptions made in the analyses, with a very brief statement of the methods used in the observations.

Reference points and readings to determine longitudinal and lateral movements of the rail along the track had been included in the program undertaken by the engineers of the railroad companies; it was thought not necessary to duplicate these observations. The method of test chosen was based on strain-gage measurements longitudinally along the web of rail (8-in. or 10-in. gage lengths) on gage lines distributed throughout the length of the stretches, with simultaneous measurement of the rail temperatures along the stretch and frequent comparison of the strain-gage with reference bars or comparators. The strain-gage measurements were made at several rail temperatures in summer and winter. The rail temperature was found, accurately and quickly, by an open-ended thermo-couple and portable potentiometer. An invar reference bar of known expansion coefficient, a short piece of rail similar to that in the track, and, later, a compensating comparator giving almost no variation in length with changes in temperature were used in the tests; temperature and temperature correction for both rail and instrumental equipment, of course, were of extreme importance in securing accuracy of data.

As an example of the distribution of the gage lines, their spacing on the mile stretch of the Bessemer and Lake Erie Railroad may be cited. Beginning at the ends of the welded stretch, gage lines were placed on both rails, at distances from ends, of 3, 10, 30, and 58½ ft; then at intervals of one rail length to the tenth rail; then at distances of two lengths to the twenty-fourth rail length; and finally at distances of four rail lengths to about the mid-point of the welded stretch. Additional gage lines were placed at points of special interest by reason of curves and other local conditions.

It was not convenient to make observations at the time of the rail laying; besides, later adjustments by track men and other changes, would have rendered data taken then of doubtful value for the purposes of the investigation. Observations were made in September, 1935, on one stretch of track of the Delaware and Hudson Railroad Corporation at Albany, N. Y., and on two stretches at Schenectady, N. Y.; the length of these welded stretches varied from 0.5 mile to 1.3 miles. Further tests on these stretches were made in January, 1936, August, 1936, and January, 1937.

Observational tests have likewise been made on the mile stretch of welded G.E.O. track of the Bessemer and Lake Erie Railroad Company near Pittsburgh, Pa., in July, 1936, and February, 1937. The rail on the Albany stretch was 130-lb and on the others, 131-lb. The alignment of these stretches contained various curves from 1° 30′ to 7 degrees. In the summer tests, rail temperatures were made as high as 120° F and, in the winter tests, observations were made at rail temperatures as low as 13° F. Tests were also made at medium temperatures. Observations in the early morning, or on cloudy days, were useful to form a basis of comparison for the changes in length in the rail. Generally, check sets of readings were made along the stretches.

A few of the results of the tests on the Bessemer and Lake Erie Railroad will give an idea of the nature of the information obtained in all the tests. In Fig. 9 are plotted the changes in length observed along the mile stretch for two representative series in summer and two in winter. The position along the stretch is shown in terms of rail lengths of 39 ft each. Naturally, the temperatures of the rail at any time varied somewhat as the conditions of shade and exposure varied, and these variations affected the stresses and the movements. The rail temperatures along the track for the series shown were 108° to 118°, 59° to 60°, 26° to 33°, and 13° to 19°, F. As the changes in length from one temperature to another are quite minute, for ease in picturing values the unit strains (inches per inch) have been translated into equivalent stress per square inch in steel for representation on Fig. 9—that is, that stress which would be developed

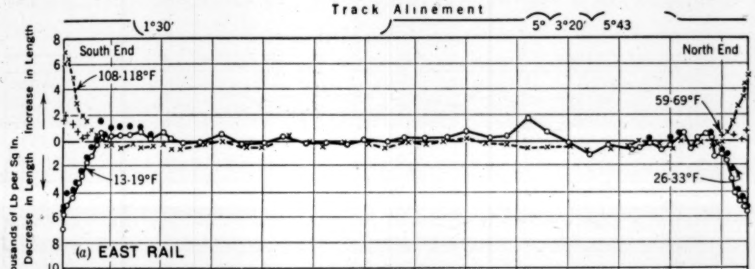

FIG. 9.—CHANGE IN LENGTH IN TERMS OF STRESS (BASE, 53° F, AND WELDED LENGTH, 1.0 MILE).

in the rail if an external force had produced the given change in length without any change in temperature. The observations before sunrise on a day in July with a rail temperature of 53° F, were taken as the basis or zero line for the diagram.

It will be noted that throughout the intermediate part of the welded stretch (about 0.9 mile) very little change occurred—only small local changes—the rail having been held closely to one length through all these variations in temperature. As the differences are generally so small, not all the points for the four series are plotted on the diagram. For the end portions of both rails, and for both the summer and the winter tests, the rails changed length through an average distance of about seven rail lengths. This change in length increases rather regularly from the points at the end of the intermediate portion (which may be thought of as the point of fixation) to the end of the welded stretch, showing a lengthening in summer and a shortening in winter, with some rounding off in the line of the end portion as it approaches the intermediate portion. The data indicate that the magnitude of the winter and summer temperatures has not particularly affected the length of track over which expansion and con-

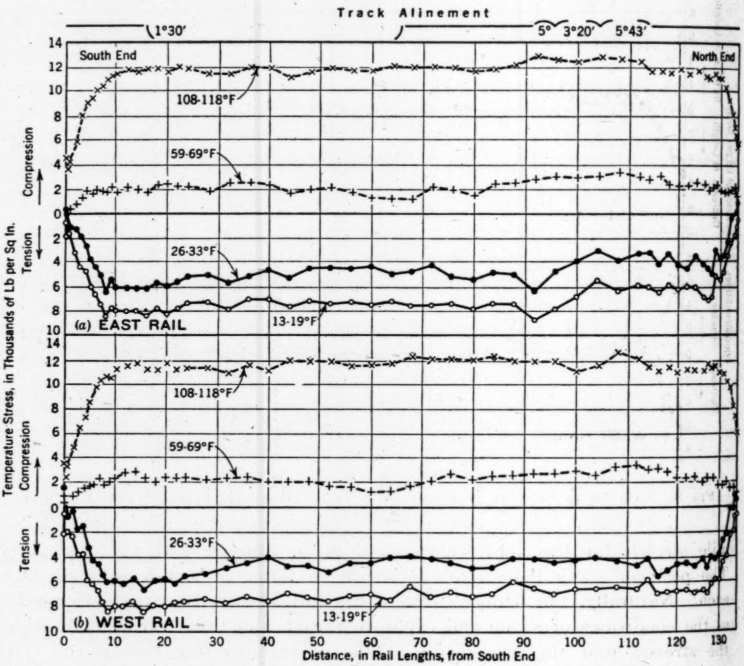

FIG. 10.—TEMPERATURE STRESSES IN RAIL (BASE, 53° F, AND WELDED LENGTH, 1.0 MILE).

traction occurs in each end portion, and that the long intermediate portion remains practically fixed in position with the various changes in temperature at the time the observations were made. It is evident that under these conditions there is no pull or drag on the ties of this intermediate portion, except as may be caused by differences in exposure and other local conditions.

In Fig 10 are recorded the stresses developed in the rail throughout the length of the stretch based on the rail temperatures and strain-gage readings at the time of observation as compared with readings at a base temperature of 53°F, which were taken before sunrise in the summer of 1936 with temperature conditions very uniform over the entire stretch. For the summer observations, at an average temperature of 113° F, the relative compressive stresses over the intermediate 0.9 mile are about 12 000 lb per sq in., and for the winter observation at a temperature of about 16° F, the relative tensile stresses average somewhat less than 8 000 lb per sq in., both values being based upon the aforementioned readings at 53° F; this means that the zero reference line represents the stress at 53° F. If the reference line were placed at 63° F, the temperature at which the rails were originally fastened in the track (the difference of 10° in temperature representing approximately 2 000 lb per sq in.), the corresponding compressive stress on the summer test would be approximately 10 000 lb per sq in. and, for the winter test, a tensile stress of approximately 10 000 lb per sq in. For summer temperatures higher than those observed and for lower winter temperatures, in accordance with other data obtained, the stress may be expected to increase in proportion to the increase in change in temperature from the 63° base. For the winter tests, the end portions show a tapering off of stress over the distance of, say, seven rail lengths to nothing at the end. For the summer tests, there was a similar tapering off in seven rail lengths to a stress of 2 000 to 6 000 lb per sq in. at the end. This end compressive stress was doubtless transmitted through the joint connecting the welded stretch to the regular track beyond. Incidentally, it may be remarked that joints have been found to transmit tensile and compressive forces to the adjacent rail equivalent to as much as 4 000 and 6 000 lb per sq in. of rail section, respectively.

The data given in Figs 9 and 10, corroborated by data of the track tests at Albany and Schenectady, indicate that within the range of temperature observed the magnitudes of the change in temperature for different series having different temperature changes do not particularly affect the length of track over which expansion and contraction takes place at each of the end portions. It is apparent, too, that the central part of the stretch has remained practically fixed in position through the summer-to-winter interval. The change in length and in stress over the end portions of about seven rail lengths, is fairly regular with some rounding off near the point of fixity, although, of course, there are changes in position from time to time at the extreme ends of the welded rail and the movement here is not always regular. The length of the end portions which give anchorage to the intermediate portion, and the stress set up in the intermediate portion correspond to an average anchorage or restraint of about 600 lb per tie per rail in each direction for the temperatures of 113° F and 16° F as counted above and below a laying temperature of 63° F. If the anchorage length remains fairly constant for temperatures above or below the aforementionad range as is indicated to be the case by the data of the various tests, the corresponding anchorage force would be proportionally greater than 600 lb.

It may be added that no indication was observable of any visible movement between the ballast and ties one way or the other at the times of the tests or of any particular change in length of the anchorage developed. It was found, however, that breakage in imperfect welds and readjustment of track in cool weather have, in places, changed the conditions of stress and anchorage considerably. It is not known, of course, what the ultimate shearing strength of the ballast bed may be. The track seems to have kept close to an elastic condition of strength.

As the data of the tests on this stretch of welded rail, and also on the other stretches tested, show that the rate of anchorage is fairly uniform over the end portions, Assumption (1) in the analyses is borne out by the tests. The tests, however, indicate that the length of the average anchorage portion remains about the same for different values of the change in temperature. This conclusion is not in accord with Assumption (2) of this discussion referred to previously as having been made by the writer in his earlier study of the problem, nor with an implied assumption of the paper that in a given track the anchorage force is a constant regardless of the value of the difference in temperature. In other words, the tests indicate that T is not the same for different values of Δt, but varies nearly as Δt.

As a consequence, it follows that Equations (8) and (9) and others in the latter part of the paper are true only when the value of T used corresponds to the given Δt. It also follows that Item (2) in the second paragraph following Theorem 1 (that the expansion varies as the square of the temperature difference for a given track) is not warranted. The tests on the tracks of the Delaware and Hudson Railroad and on those of the Bessemer and Lake Erie Railroad indicate that the expansion at the end of the welded stretch varies as the first power of the change in temperature rather than as the square, and also that the length required to develop the force, F, is largely independent of the magnitude of the change in temperature, referring, of course, to more than slight changes in temperature. Care should be taken in the use of the formulas given in the remainder of the paper where the reader may be led to think that T is implicitly used as constant for a given track. Caution in this respect is suggested in the use of Equations (18), (20), and (21). It may be implied from the wording in Example 4 that the value of T is the same for a temperature change of 100 ° F as for one of 58° F. This assumption is not in accord with the results obtained in the Stresses in Track Investigation. These several inaccuracies in the analysis and its applications affect the usefulness of the "theory" in a way that seems to warrant calling the attention of the reader to them.

These comments are made in the light of what has been learned so far in the observational tests of four stretches of long welded track, all of which are in a sense experimental. It is planned to continue the seasonal tests to learn the changes that occur at later dates when time and traffic may have had their effects. As stated by Mr. Africano further fundamental knowledge of the physical action of welded rail in track is needed. It will take time to secure this information. Much more must be learned of welds before welded track, with its higher investment in welds and substructure, will be generally accepted as a standard for high-grade track. That interest has been aroused in this type of construction is shown by the starting of an investigation on continuous welded rail at the Engineering Experiment Station, University of Illinois, through a co-operative agreement with the American Railway Engineering Association and the Association of American Railroads. The investigators will study the strength, ductility, and durability of continuous welded rails made by different processes. They will doubtless find the quality and uniformity of the metal at the welds and at each side of them as well as the uniformity of surface and line and the wear of the joint under repeated rolling loads for both sample joints and joints cut from track.

It may not be out of place to suggest that Mr. Africano's recognition of the desirability of giving the track anchorage throughout the entire length of the welded stretch might well be made much stronger. Without continuous rigid support, breakage of rail in the intermediate portion of the welded stretch and other accidental events might lead to serious trouble. To make a further comment: The coefficient of linear expansion of steel varies over quite a range; the International Critical Tables give values in the range of rail steel from 0.0000055 to 0.0000072. For 131-lb rail tested at the University of Illinois, Urbana, Ill., the coefficient was found to be 0.0000063. This differs appreciably from the value, 0.0000073, given in the paper.

The author is to be commended for putting forth an analysis in a new field, even without having adequate experimental evidence of the action of continuous rail in railroad track.

Randon Ferguson,[22] Assoc. M. Am. Soc. C. E. (by letter).—As a member of the test party of the Special Committee on Stresses in Railroad Track of the Society and the American Railway Engineering Association, the writer has been engaged on tests on several sections of long welded track. A short discussion on some of these tests has been published elsewhere.[23] Further discussion and description of various installations are also available in the reports of the Committee on Rail of the American Railway Engineering Association.[24]

Although the tests are not complete at the present time certain comments of a tentative nature may be made as to the results. It is doubtful whether the nature of the tie resistance is frictional, as assumed by the author. A frictional resistance would imply that the value of the tie resistance, *T*, is a constant for any given track for all temperature changes if end movement occurs, as it apparently does, and that the length of track giving anchorage would depend on the temperature change. Instead, the tests on the track of the Delaware and Hudson Railroad Company and the Bessemer and Lake Erie Railroad Company indicate that the degree of tie anchorage on a given track varies with the magnitude of the temperature change, and that the length of track giving anchorage remains constant for all changes of temperature both winter and summer. The tie resistance has also been found to vary somewhat near the ends for a given temperature; or, in other words, the force or stress diagram is not necessarily a straight line, as the author indicates in Equation (3). The tracks tested have been found to be quite completely anchored except for the end portions where the periodic expansion or contraction due to temperature occurs over a distance of about five to twenty 39-ft rail lengths.

[22] Asst. Engr., Assoc. of Am. Railroads, Univ. of Illinois, Urbana, Ill.

[23] *Proceedings*, A. R. E. A., Vol. 37, 1936, p. 954.

[24] *Loc. cit.*, p. 465; and, also, *Bulletin 393*, A. R. E. A., p. 493.

It should be stated for the benefit of readers who are not intimately familiar with the existing installations of continuously welded rail, that as far as known all installations of welded track for standard railroad service have special fittings designed to anchor the rail firmly to each tie. A clip and bolt fastens the rail to the tie-plate on both sides of the rail and the tie-plate is fastened to the tie with screw spikes. This greatly increases the available longitudinal restraint as compared with the usual practice of applying three to six rail anchors per rail. Ordinarily, the rail anchors are effective in one direction only. Of course, the fastenings must be provided over the entire stretch whether or not they are doing any work. Any rail breakage, in a weld or elsewhere, at once requires the track adjacent to the break to be capable of withstanding forces of the same magnitude as those occurring at the normal end portions.

The tests have indicated the development of tie resistances of about 600 lb per tie per rail in each direction, with a rail temperature range of 50° above or below the laying temperature. The limiting value of the tie restraint is not known from the tests. Any appreciable slippage observed has been through the clips, and this occurred in a few cases when a rail broke or the end joints were loosened for adjustment. The ballast in all cases was snugly bedded against the ties with no evidence of the tie working back and forth along the track.

The range of temperature of the rail may be as much as 150° over a period of a year. In the absence of sunlight or protective covering, such as snow, the rail follows the air temperature quite closely. On a bright day, either winter or summer, the rail may be as much as 40° warmer than the air temperature if there is no breeze. With snow around the rail, the rail temperature has been found to be 10° to 15° warmer than the air temperature, thus minimizing the effect of low air temperatures.

A. N. Reece,[25] M. Am. Soc. C. E. (by letter).—In directing attention to factors influencing the amount of rail expansion, that have quite generally been neglected in the past by engineers in the United States, this paper serves a useful purpose. Not only does the new theory that Mr. Africano describes apply to long welded rail installations on the rigid type of track, but it shows equally well that expansion requirements for rails of ordinary length, secured only with cut-spike rail fastenings, are appreciably less than the theoretical requirements based upon the assumption that the rail is free to expand without restraint.

For example, in a 131-lb rail having a cross-sectional area of 12.86 sq in., a force of $12.86 \times 0.0000065 \times 30\,000\,000 = 2\,500$ lb, is required to restrain the rail fully through a temperature change of 1° F. Assuming that six-hole joint bars, with bolts tightened, will develop sufficient frictional resistance so that a force of 75 000 lb is required to slip the rails within the bars, then, for a temperature increase or decrease of $\frac{75\,000}{2\,500}$, or 30° F, there would be no rail end movement. This joint restraint would then be sufficient to prevent rail expansion or contraction through 60° of the seasonal variation in rail temperature, or almost throughout one-half the range. Thus, only one-half the expansion allowance, calculated for the rail without restraint, need be allowed. To secure full advantage of this condition, however, it would be necessary to lay the rail at temperatures ranging from less than 30° of the maximum to more than 30° of the minimum.

The use of longer and continuously welded rail offers a prospect of material improvement in the track structures, and studies, such as that of the author, are invaluable in acquainting engineers with a new field into which they are destined to "travel."

G. M. Magee, Esq.[26] (by letter).—In recent years, the expansive action of rails subject to joint and tie restraint has been given intensive study in Germany by several investigators. In addition to theoretical analyses of the temperature change and restraining forces, considerable research work was conducted to determine the actual values of joint and tie restraints. The adoption of a new track construction as standard on the German National Railways in 1925, provided a tie-plate fastened to each tie with four screw spikes, a compressed wooden shim between rail and plate, and a firm fastening of rail to each plate by two clamp bolts, clamps, and double-coil spring washers. This construction has also been introduced in the United States.

It was found that with this type of fastening, the rail did not slip through the plate, but that where longitudinal movement of the rail did occur, the rail, ties, and ballast within the cribs moved as a unit, presumably slipping along a horizontal plane at the bottom of the ties. In 1929, Ammann described[27] an interesting experiment in which a panel of track was especially constructed on crushed rock ballast, a concrete buttress placed at one end, and known longitudinal forces applied to the rail ends by hydraulic jacks, in order to determine the tie resistance to longitudinal movement of the rail. Later investigations were made on track in traffic use and under different weather conditions. A tie resistance of 881 lb per running meter of rail was observed for 24 wooden ties per 15-m rail length.

[26] Asst. Engr., Kansas City Southern Ry., Kansas City, Mo.

As a result of the analysis of expansion movement with proper consideration of tie and joint restraint the rail lengths in use on this type of track construction were generally increased from 15 to 30 m (approximately, 49 to 98 ft, respectively) by welding two rails when the old rail was serviceable, or by purchasing new rail of 30-m length. Trial installations were also placed of 60 and 120-m lengths.

Long welded installations of rail have been placed in open track in the United States on two railroads. The first installations were placed on the Delaware and Hudson Railroad, using a type of construction similar in principle to the German fastening, but differing principally in that two spring clips and bolts secured the rail to the tie-plate and no shims were used. An installation of long welded rail has also been placed on the Bessemer and Lake Erie Railroad, using the German type of construction.

The new theory of rail expansion described by Mr. Africano explains the apparent phenomena of placing rail with no provision for expansion and shows that, in this welded construction, expansion movements may be analyzed by known engineering principles.

Although, as Mr. Africano points out, the rigid rail fastenings are required only at the ends of long welded rail to restrain the expansion, it should not be thought that these fastenings are not needed at the intervening ties. Their function is a highly valuable one at the intervening ties to prevent excessive opening of the rail in the event of rail breakage in cold weather and to resist track buckling in hot weather. Should the track begin to buckle at a point of weakness, the rail is held from running into this point of weakness and a "sun-kink" is thus prevented in its beginning stages.

The rail stresses due to restraint of the expansion must not be disregarded. Should rail be laid, welded, and secured in the hottest weather, a maximum tension stress due to temperature effects in the coldest weather of approximately 30 000 lb per sq in. should be anticipated. This would be additive to the rail bending stresses and would place too large an added burden on the rail. The laying of this type of track at mean temperatures would equalize the disadvantages of stress due to rail tension in winter and track-buckling forces in summer. The maximum rail-tension stress of 15 000 lb per sq in., due to temperature effect, which would be developed in this method of laying, is probably not too severe for the heavier rail sections that weigh 131 lb per yd, or more.

[27] "Latest Investigations in Regard to the Effect Which the Longitudinal Forces Exert on the Rails", by Prof. Dr.-Ing. Ammann, Karlsruhe, Germany, *Technical Weekly Traffic Review*, Issue No. 47, Berlin, November 20, 1929.

The effect that wave action of traffic may have on tie resistances for long welded track are not yet well determined. Preliminary measurements indicate that with traffic in one direction, the rail is likely to show somewhat more movement at one end of the long welded rail than at the other. It does not seem, however, that this will appreciably alter the analytical determinations.

There is also some question as to whether the tie resistance to horizontal movement may be considered as an elastic resistance similar to the modulus of track resistance, *u*, to vertical depression. It is to be expected that the tie resistance is more in the nature of a frictional, rather than of an elastic, resistance.

The author is to be commended for his invaluable analysis of this new and important subject.

H. D. HUSSEY,[28] M. AM. SOC. C. E. (by letter).—The assumption is made in this paper that long welded rails are laid in tangent, level track, and the author has developed a method of computing the stress in the rails and the end expansion, for a change in temperature and a known tie resistance. When the rails are laid on a curved alignment, the radial component of the stress in the rails produces a force which tends to displace the ties laterally. This radial force on each tie is:

$$F_r = \frac{2\,s\,A\,c}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (29)$$

in which, in addition to the notation of the paper, F_r = radial force on one tie, in pounds; and r = radius of curvature. Mr. Africano has demonstrated that $s = 219$ lb per sq in. for 1° change in temperature. It is seen that F_r decreases as the radius of curvature increases, and that, in a straight track, it becomes equal to zero. For example, assume that 131-lb rails are laid on a 1° curve and that the tie-spacing, *c*, is 22 in. Then, by Equation (29), $F_r = 1.80$ lb for 1° change in temperature. For 100° change in temperature, $F_r = 180$ lb. This force must be added to (or subtracted from) the radial force on the tie that is due to a train passing around the curve. When the temperature is higher than that at which the rails were laid, these forces will be additive, but when it is lower, they will counteract each other.

Equation (29) can be used in the computation of vertical forces exerted by rails that are curved in a vertical direction, as in the case of vertical curves at the top of a hill or the bottom of a valley. A horizontal and a vertical curve occurring at the same point is an unfavorable combination.

Research on long welded rails should include the determination of the lateral resistance of ties in track on curved alignment and the action of curved rails.

---

[28] Designing Engr., Am. Bridge Co., New York, N. Y.

ALFRED AFRICANO,[29] ASSOC. M. AM. SOC. C. E. (by letter).—Those who have been kind enough to discuss this paper have added immeasurably to its value by clarifying some points perhaps too briefly treated, by contributing their experience with continuous welded rail in support of the theoretical analysis, and, finally (and of equal importance), by emphasizing certain objections to the fundamental assumptions made.

Although most of the discussion indicates an acceptance of the simple mathematical derivation of the formulas as valid for practical purposes (leaving to the judgment of the engineer who uses them the determination of the best average resistance, T, per tie—as the writer intended), the objections offered by Professor Talbot seem sufficiently important to be given first attention.

Of the questions which Professor Talbot raises the principal one seems to be the uncertainty as to whether or not the longitudinal resistance set up at each tie is a constant. It is not a constant. It varies under the influence of so many factors that the writer purposely avoided attempting to assign any quantitative value to those factors at all. If a simplifying average or effective value of the tie resistance under all conditions can be used in such a manner that the theoretical analysis will show a practical agreement with observed end movements, its use is obviously justified.

The experimental data given for the two half-mile rails of the Delaware and Hudson Railroad Company at Mechanicville, N. Y., were the average of forty reported observations of end movements made over a period of 1 yr, for various temperature changes. It is extremely interesting and instructive to plot these individual results against Δt, the temperature change in degrees Fahrenheit from the rail-laying temperature. This has been done in Fig. 11(a). For comparison, the curves of theoretical end movements obtained by the use of Equations (9) and (18) are also shown.

The scattering of the observed points indicates the difficulty of attempting to formulate an exact equation accounting for every variation and, consequently, the desirability of using the simplest possible analysis that will give practical results. Equation (9), based on a constant value for T, apparently gives such results. The important consideration here is that the theoretical or predicted expansion or contraction is approximately 1 in., as observed for the ordinary range of temperature change, and not the large value heretofore calculated by assuming free expansion. That the fear of dangerous free expansion actually existed at the time these rails were laid, is proved by the fact that an elaborate expansion joint was provided by the engineers of the Delaware and Hudson Railroad Company to take up the maximum of 22-in. end movement computed in this way if one end remained fixed and the other received the total expansion.

Equation (9) is plotted with $T = 2\,100$, whereas Equation (18) is plotted with $T = 600$ and a joint restraint of 35 000 lb, or about 3 000 lb per sq in. transmitted by the joint (averaged from Fig. 10 given in Professor Talbot's discussion).

Although joint restraint no doubt exists, it is too erratic to be depended upon and, in the writer's opinion, should not be used at all in designing fasten-

(*a*) HALF-MILE RAILS AT MECHANICVILLE, N.Y.; BASE TEMPERATURE 90° F.

(*b*) ONE-MILE RAIL AT VALLEY RIVER, PA; BASE TEMPERATURE 38° F.

FIG. 11.—COMPARISON OF THEORETICAL WITH OBSERVED END MOVEMENTS OF LONG RAILS

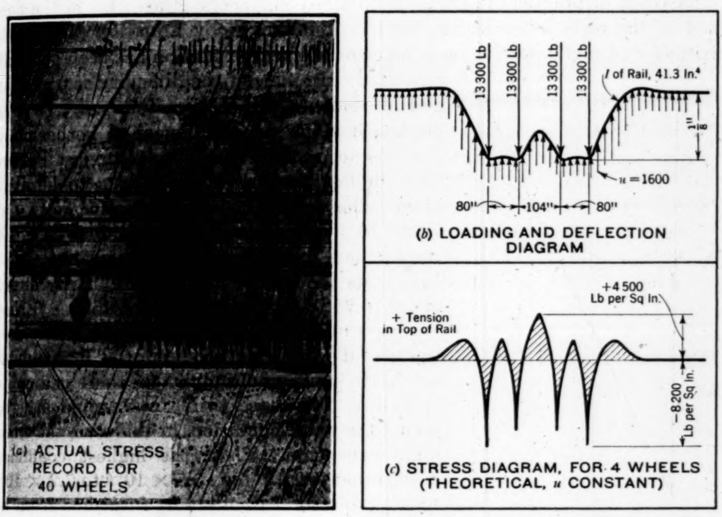
ings and track for new installations, since the really serious situation occurs when a rail breaks, giving the condition of two free-rail ends. By controlling the value of the tie resistance in future installations the magnitude of the resulting gap can also be controlled. In Fig. 11(*a*), a value of 2 100 in Equation (9) shows a better agreement with the observed data than the value of 600 in Equation (18) with any magnitude of joint restraint. The high value also gives a better basis for explaining why the gaps were only 1 in. or 2 in. when rails broke instead of the 3 in. to 6 in. that should be expected if only the lower value was available.

It should be noted that the writer did not arbitrarily assign or "place" the high value of 2 100 lb for T for the reason Mr. Hunt suggests, but solved for the average value that must have been effective at various temperatures to produce the evident correlation with the small observed end movements.

From additional experimental data made available since 1935, when the paper was written, the writer plotted Fig. 11(*b*) showing a comparison of theoretical with observed end movements for the one-mile continuous welded rail installed by the Bessemer and Lake Erie Railroad Company, at Valley River, Pa. The agreement is as good as can be expected for so variable a structure as a railroad track, and the scattering of the points again precludes the use of any assumption other than simple constant tie resistance. It should be noted that very little joint resistance must have existed since Equation (9) passing through the origin obviously fits the data better than Equation (18). The latter would cut the horizontal axis at some particular value of temperature change determined by the degree of joint resistance which acts to prevent any movement until that temperature change is exceeded. No distinction has been made in this graph (Fig. 11) between movements (expansions) corresponding to positive temperature changes and movements (contractions) corresponding to negative temperature changes. The writer agrees with Professor Talbot qualitatively in believing that the direction of the temperature change, up or down, as well as the magnitude, exerts some influence on the available tie resistance. Quantitatively, however, to judge from Fig. 11(*b*), it would seem scarcely worth evaluating.

Use of a simplifying assumption for practical purposes under such circumstances is by no means without precedent. As Chairman of the Special Committee on Stresses in Railroad Track, already referred to, Professor Talbot used an analogous simplification in the case of the exceedingly variable vertical modulus of foundation, or rail support, u, in the development of the equation for rail stress due to static wheel loads.[5] Those familiar with this equation know how variable this modulus may be in different tracks and even from point to point in the same track. When the writer began investigating rail stresses in the tracks of the Interborough Rapid Transit Company, in 1931, he found by studying the reports of the Committee on Stresses in Railroad Track and by correspondence with authors of papers on rail stresses, that although the extreme variation in individual values of this assumed constant was generally acknowledged, the results obtained from the assumption were sufficiently close to actual observed stresses to warrant the method.

To illustrate this point, the similarity is shown in Fig. 12 between actual stresses measured by the writer in 1934 with a scratch extensometer and the theoretical static stresses from Equation (24) by using a constant value of $u = 1\,600$ and superimposing stresses due to the four wheels. The scratch record was made while the 10-car train passed slowly over the instrument, recording actual strains in the steel, and later was magnified 100 times and photographed. Since the recorded stress represents the effect of different values of the vertical elasticity of the track, the agreement based on a constant value is surprisingly good.



(a) ACTUAL STRESS RECORD FOR 40 WHEELS

(b) LOADING AND DEFLECTION DIAGRAM

(c) STRESS DIAGRAM, FOR 4 WHEELS (THEORETICAL, u CONSTANT)

FIG. 12.—ILLUSTRATION OF ANALOGOUS CASE IN WHICH MODULUS OF FOUNDATION, u, AS A CONSTANT GIVES PRACTICAL RESULTS FOR RAIL STRESSES DUE TO WHEEL LOADS

Referring again to Fig. 10, an independent conclusion may be reached as to whether or not the tie resistance varied appreciably for the same, and for different, temperature changes. If it is constant, the accumulating longitudinal force should increase uniformly along a straight line, and this the graph shows.

By noting that the slopes of the lines showing the accumulating stress in Fig. 10 are approximately 30° from the vertical, for three of the four temperature changes shown, the conclusion may be drawn that, as far as practical results are concerned, this assumption is valid for all temperature changes. The rounding off near the top of the sloped line is to be expected, since, as the writer was careful to point out, there is no doubt a slight effect, more pronounced at this point, of the longitudinal resistance being proportional to the longitudinal movement. As the accumulating resisting force approaches that required to fix the rail completely, the movement of the rail diminishes to so small an amount that the tie resistance does not have a chance to come into action, especially if there is any looseness in the ties. In other words, there may be a limiting degree of movement above which the tie resistance is fairly constant and below which the longitudinal restraint is more nearly proportional to the rail movement. In the writer's opinion, the latter effect is a negligible factor in the computation of the end movement.

A point of practical importance to many engineers—the stress in the fixed part of the rail—seems satisfactorily taken care of by Equation (2), but the writer's choice of value for the coefficient of linear expansion has been generally criticized. In view of the difficulty of predicting end movements within more than, say, 75% accuracy, it seems poor judgment to bother about extreme accuracy in this one factor just because more or less precise values happen to be available. The writer chose the value for hard steel, 7.3×10^{-6}, given in the steel handbooks, not to recommend its use particularly, but because it better fits the case of rail steel ordinarily having about 0.75% of carbon with a higher Brinell hardness number than the structural steel which has about 0.33% carbon and the lower value, 6.5×10^{-6}. In addition, where there is a choice of values, the conservative one would be that giving the worst condition, in this case, the maximum expansion. Thus, the highest coefficient in the range for rail steel, 5.5×10^{-6} to 7.2×10^{-6}, which Professor Talbot kindly furnished from the International Critical Tables, should unquestionably be used.

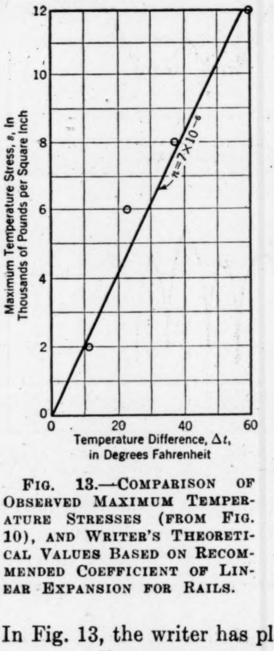


FIG. 13.—COMPARISON OF OBSERVED MAXIMUM TEMPERATURE STRESSES (FROM FIG. 10), AND WRITER'S THEORETICAL VALUES BASED ON RECOMMENDED COEFFICIENT OF LINEAR EXPANSION FOR RAILS.

The handbook value for hard steel checks this maximum coefficient very closely. From the temperature stresses for the fixed part of the rail shown in Fig. 10, it is possible to compute an average value for actual track conditions. In Fig. 13, the writer has plotted the observed temperature stress against the corresponding average temperature differences from the base of 53° F for each case, choosing the straight line that passed nearest the data as the best stress-temperature relationship. The slope of this line is the same as that for the straight-line Equation (2), or $E\,n$. Substituting a constant value of 30 000 000 for E, and solving for n results in the value, $n = 7 \times 10^{-6}$, for the best actual track value of the coefficient of linear expansion in these cases, as against the laboratory test value of 6.3×10^{-6} which Professor Talbot favors. This calculation corroborates the higher value used by the writer, and, in his opinion, shows that the inaccuracy involved is not only negligible, but that the round value of 7×10^{-6} is entirely adequate for the degree of precision warranted and should be used in all computations of end movements for long rails.

The remaining points raised by Professor Talbot can be considered more briefly. It is to be expected that the special problems involved in the maintenance of long welded rails will have to be solved satisfactorily before they come into general use. Nevertheless, since it is known that they do not expand or contract as free rails, and have been in actual use for several years, as pointed out in Mr. Baldridge's valuable contribution of historical background, they are no longer experimental except for these problems. If this paper serves only to show to the Engineering Profession that the existing statistical evidence in favor of the practicability of long welded rails is supported by known engineering principles even if the theoretical analysis may not be completely satisfactory, the writer's intention has been fulfilled.

Regarding the use of calculus for deriving what proves to be a simple second degree equation, this is the usual method for determining the integral or total effect of a variable factor.[30] The writer took special care to show every step of the precise reasoning upon which the resulting formulas are developed. It may seem unnecessary to those who have devoted years of study to a specialized subject.

Figs. 9 and 10 are important in showing conclusively the existence of the fixed intermediate part of the rail as predicted by the photographs of the writer's elastic model shown in Fig. 2. The use of "equivalent stress per square inch" for the measured unit change in length may be confusing to some readers. Since a temperature change requires the length to change to avoid becoming stressed, it might have been more informative to plot the actual data to some convenient scale, especially since its use is desired for developing a general principle. Such data, if obtained near the ends of an intentionally broken rail, along with the corresponding end movements would yield valuable information on the actual maximum holding power of the rail fastenings.

In cautioning readers in the use of Equations (18), (20), or (21) (or for that matter any equation or its application), the writer heartily concurs with Professor Talbot. Both the derivation of the equations and their applications, the writer agrees, are too new to be plucked blindly from a handbook. It is of equal importance to point out that inaccuracies may be conceded to exist, and yet be so negligible as not to affect the usefulness of the theory for all practical purposes.

Mr. Gailor appears to be satisfied with the calculations and formulas as a basis for future studies but states that the possible out-of-alignment of a long rail on a hot day is a different condition from the straight line assumed in the paper. It is true that for the purpose of analysis the writer used the case of straight tangent track. However, even if the rail is laid in the winter, which is not recommended, the buckling that may be caused vertically and laterally by excessive expansion the following summer is not likely to affect the end movement appreciably, and remains as a problem to be solved by providing proper lateral resistance.

Statement (6) by Mr. Gailor seems to show a misinterpretation of one of the fundamental points of the analysis, namely, that the temperature stress set up in a rail when fixed is independent of the length and would be the same whether for one tie-spacing or for one mile. Since it may be of the order of

---

[30] "Mechanics of Materials," by L. A. Martin, p. 16. Here a similar use of calculus is made to determine the extension of a cylindrical rod due to its own weight. The interesting and analogous result is that the extension is one-half that which would occur if the total weight were concentrated at the lower end.

200 000 lb it is impossible for any single tie-fastening to resist. The cumulative resistance is the only remaining explanation for the fact that such large forces must have been developed to restrain the long rails in present use. This cumulative feature of the tie restraint has been well established by the experience presented in several of the discussions.

The writer regrets having given the impression that he would have considered using rigid fastenings at the end portions only; yet according to the data submitted by Mr. Walker in Table 5, even ordinary spike fastenings prevented the ends of broken rails from separating "in excess of 2 in." so that the fear of "disastrous results" expressed by Mr. Gailor and Professor Talbot in such a case seems to be unfounded. However, the writer would recommend using some relatively economical type of rigid fastening for the mid-section and the best available rigid fastenings at the ends. In this way the definite end movements occurring with temperature changes are reduced to a minimum, thus avoiding trouble with the insulated joints which, to a great extent, will determine the practical maximum lengths of welded rail. The number of rail breaks for standard rail is of the order of 1 per track-mile in 5 yr of service. The temperature stress may increase this, but it will depend on the experience and judgment of the engineer as to what degree of rigidity and extra expense he will consider absolutely necessary to offset the risk of this occasional failure.

Mr. Kenney believes the vital problem is not so much the control of linear expansion as the control of lateral expansion without, possibly, increasing the maintenance cost. Since the scope of the paper was limited to the discussion of temperature stresses and rail expansion the writer will not attempt to prove any economy in the use of welded rail. Such conclusions depend to a great extent on the additional life of the rail due to elimination of end batter, and this factor requires several years to determine statistically.

The case mentioned by Mr. Baldridge of the shearing of joint bolts following a sudden drop in temperature is significant as it indicates the need for investigating even existing standard track for the possibility that it may act as a continuous rail. The writer has observed frequent cases in which rails have "ganged up" or closed their gaps in warm weather and then have acted as a unit in ensuing cold weather, in one case permitting a gap to open almost an inch.

Applying the analysis to the data given by Mr. Baldridge of a 2.5-in. maximum gap opening for a temperature difference of 100° F it is possible to estimate the length of anchorage and the average tie-resistance that had to come into action in this case. A 2.5-in. gap means that 1.25 in. of contraction occurred in the critical length on each side of the joint. This is the free expansion for 160 ft of rail, as Mr. Baldridge calculates, by substituting $\Delta l = 1.25$ in., $n = 6.5 \times 10^{-6}$, and $\Delta t = 100°$ F, in Equation (1), and solving for l. However, this length, l, represents expansion or contraction without restraint, and since the actual degree of expansion varies from that for a free rail at the gap end, to zero at the opposite fixed end, the average rate of expansion is only one-half the free expansion as the writer demonstrates by Equation (9) and Theorem 1 in the paper. Consequently, the length of the anchorage must have been twice 160 ft, or 320 ft, on each side of the joint.

Assuming 2-ft tie-spacing, the average longitudinal resistance of 160 ties will be available to equal the total temperature stress set up when the rail is finally fixed. The unit stress from Equation (2) is 19 500 lb per sq in., if n is taken as 6.5×10^{-6} and E, as 30×10^{6}. Multiplying by the area of the 112-lb rail (11.05 sq in.), the total temperature stress to be resisted by the ties is about 216 000 lb, which, divided by the 160 ties, gives as the probable effective resistance of each tie 1 300 lb. Equation (9) would have given this value immediately since all other quantities are known.

Mr. Hunt emphasizes the fact noted by the writer that Equation (9) is simply a special case of Equation (18) when the joint resistance, P, is equal to zero. He contributes a useful graphical solution in Fig. 5 for this general case. The writer developed the "special" case first for two good reasons: It is logical to start with the simplest case; and since this tells the maintenance-of-way engineer what maximum gap opening to expect, it is the most important case.

Table 3 is useful to show the effect of joint restraint on the calculated value of the tie resistance. Both Messrs. Hunt and Magee believe the influence of joint restraint was under-estimated, thus leading the writer to what may be considered too high a value for T in the illustrative examples. These examples show that two different values may be obtained by using a definite joint restraint and by considering the gap at a free end. Hence, it should follow that the correct application of Equation (18) at a joint to determine the tie restraint depends upon an accurate knowledge of the degree of joint restraint. It is much simpler to obtain accurate values for the maximum available tie resistances, by reproducing the condition of a free end. Thus, by loosening the joint bolts and noting the free end movement, the elementary Equation (9) can be applied. Purposely breaking the long rail at some point on the fixed length would be an accurate method of obtaining the data to guard against such an accidental contingency. The effect of the joint restraint on the magnitude of the temperature stress seems of little importance since this stress becomes a maximum in the fixed part of the rail regardless of whether or not joint restraint exists. Its only effect on the end movement is to decrease it.

In Table 4 Mr. Hunt demonstrates that an 8-in. gap might result if ordinary track were made continuous. The actual data submitted in one of the discussions for such track showed that the gaps were much smaller so that a higher restraining force must be considered to have been in effect. His calculations and diagrams showing the local stresses set up when a short length of a long rail under temperature stress is replaced, are interesting, but such stresses may not be serious since they would have a good chance of being "ironed" out by vibration and wave action in the rails due to the wheel loads. Creeping of rails produces a similar effect and is no doubt responsible for some of the scattering in the observed points in Fig. 11.

Mr. Walker's photograph of the "sun-kink" (Fig. 8) on a welded rail is extremely interesting, and his experience in eliminating this trouble in the 210 miles of unpaved welded track of the Eastern Massachusetts Street Railway, is a valuable addition to the paper. He reports that the actual expansion in the 660-ft lengths was about one-half the expected 6 in., thus checking the phenomena observed in the Victorian Railways in Australia and corroborating

Theorem 1. The incident of the rail "popping out" of the remaining spikes after some had been removed is worth noting, both for the warning it gives of this possible source of danger, and as an illustration of how the total resisting force is an accumulation of many small forces.

Mr. Ferguson's objections to the use of a uniformly increasing anchorage due to constant tie resistance are similar to those of Professor Talbot which have already been considered. He is correct in stating "the force or stress diagram is not necessarily a straight line"; but the straight line, nevertheless, seems appropriate for the analysis.

Mr. Reece's numerical example showing how joint restraint may cause even short rails to expand and contract less than they would if free is of special interest to those who have noticed discrepancies with the expected gaps based on the standard tables for rail laying.

Mr. Magee agrees that the tie resistance is more in the nature of a frictional than an elastic resistance. To explain end movement where no surface evidence of movement is noticeable, he suggests that slippage may occur along the horizontal plane at the bottom of the ties—the rail, ties, and ballast moving as a unit. However, cases are on record in which sliding of the rail occurred through the fastenings, particularly when the temperature dropped suddenly and the rail broke.

A question frequently raised regarding the magnitude of the buckling forces in curved rail due to temperature stresses is answered by Mr. Hussey's Equation (29) which gives the required radial resisting force in each tie to keep the rail in place. It should be stated that this equation involves the assumption that the half-chord of the curve enclosing two tie spans is equal to the tie span, *c*. This is a close approximation. Radial forces of about the same order may exist when the speed of a train around a curve exceeds that corresponding to the superelevation. The same lateral rail anchors that are already in use for the one radial force may be sufficient to hold the additional radial force due to temperature stress, at least for curves of large radius. For sharper curves, this effect might become serious, and the added factor of a shorter life may make welded rail inadvisable in certain cases.

In the writer's opinion the entire track structure of the future will be altered radically from that called "standard" to-day in the effort to obtain the maximum economy and the smoothest riding from continuous welded rail. A continuous elastic support under the rail in addition to adequate cross-members and a concrete sub-grade should do much as an approach to the more rational structural unit required to parallel the advances made in modern stream-lined trains.

Paper No. 1992

ECONOMICS OF HIGHWAY-BRIDGE FLOORINGS OF VARIOUS UNIT WEIGHTS

By J. A. L. WADDELL,[1] HON. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JONATHAN JONES, HENRY C. TAMMEN, MILLER McCLINTOCK, JOSEPH G. SHRYOCK, C. CALOR MOTA, W. G. FOWLER, PHILIP A. FRANKLIN, AND J. A. L. WADDELL.

SYNOPSIS

The comparative economics of any two or more types of modern highway-bridge floors is presented in this paper. The method provides a means of answering questions of relative economy in a very few minutes, beyond the peradventure of doubt in regard to accuracy, either to-day or at any future time. The following information concerning each competing type must be known: The thickness of the flooring and its weight per square foot; the weight of metal per square foot of floor, between the stringers and the flooring with a stringer spacing of 5 ft, if there is any such special metal (or, otherwise, the extra weight of metal per square foot, in the floor system, due to a closer spacing of stringers); and the cost per square foot of flooring in place.

Figs. 1 to 8, with Table 1, afford all the information required for making such economic comparisons; and the text describes the conditions that governed the computations for all diagrams and tables. Invariably, both superstructure and substructure costs are considered, under the average or the usual conditions that were assumed for the latter.

Certain unit prices of materials in place were adopted for making the calculations of total costs per linear foot for the more than two hundred and fifty spans that were specially computed in making the investigation. Due cognizance was taken of the fact that the unit prices of both superstructure and substructure material, in place, increase as the total quantities thereof diminish; and certain empirical formulas are furnished for the proper and adequate correction (for this reason) of all such unit prices.

NOTE.—Published in February, 1937, *Proceedings*.

[1] Cons. Engr., New York, N. Y. Mr. Waddell died March 3, 1938.

The bridges covered in the records are for simple-truss and cantilever spans, for both wide and narrow roadways, and for both carbon-steel and silicon-steel structures. Attention was paid, wherever necessary, to the augmenting of total metal weights due to wind loads, and to the effect on costs of both superstructure and substructure from the spreading of trusses beyond the requirement for width of roadway. The curves were determined upon the basis of there being solid rock or an equivalent reasonably hard foundation for piers; and the effect on the comparative economies of using pile foundations has been treated.

Full explanations are provided regarding the utilization of the diagrams and tables; and three practical cases for bridge-floor competitions have been solved in the text. The economic effects of using light floorings on vertical-lift and bascule spans and on suspension bridges have been treated at some length. The entire investigation has been made upon an absolutely unbiased basis; and the method of presenting the cost diagrams represents the acme of impartiality.

INTRODUCTION

In addition to the usual type of reinforced concrete flooring for modern highway bridges, termed herein the "Standard", there are a number of patented floorings, the main object of which is to reduce the dead load on the structure and thus save metal and, therefore, expense. Because these special types are more costly than the ordinary type of reinforced concrete flooring, and, in addition, involve royalties, they are likely to increase rather than to decrease the total cost of structure in short-span bridges.

Other considerations being equal (that is, ignoring all claims for superiority of surface, resistance to skidding, absence of pitch or crown, better drainage, non-collection of snow and ice, etc.), the bridge engineer, in the interests of his clients, will very properly desire to design his structures so as to keep their total cost down to a minimum by selecting the most economic type of flooring. Each patent owner naturally wants people to believe that his special type is not only superior to all other types, but is also the least expensive, when the total cost of the completed structure is in question. Comparing any two types of equal suitability, it is evident that the lighter the flooring the smaller will be the percentage of steel required for both the floor system and the trusses; but the total saving of metal may not be great enough to offset the difference in the costs of flooring for the two types under comparison, after the royalties have been included.

It is evident that the longer the span the greater is the proportionate saving in metal weight of trusses resulting from the reduced dead load. As far as the different types of floor construction are concerned, it is almost axiomatic that the lighter the flooring the greater, generally, is (or should be) its actual cost per unit of area, because the thinner it is the larger must be its volume of expensive steel and the smaller its volume of cheap concrete. This statement does not always apply to varying thicknesses of flooring of the same type.

Since, at present (1937), few, if any, bridge specialists are at all certain about the comparative ultimate economics of the various bridge floorings, the establishment of an absolutely correct and impartial method for settling the question would be a real boon, not only to the Engineering Profession, but also to the promoters of bridge projects and to the financiers whose money is to be spent for the materialization of the desired structures. It is for that reason that this paper, with Figs. 1 to 8, has been prepared.

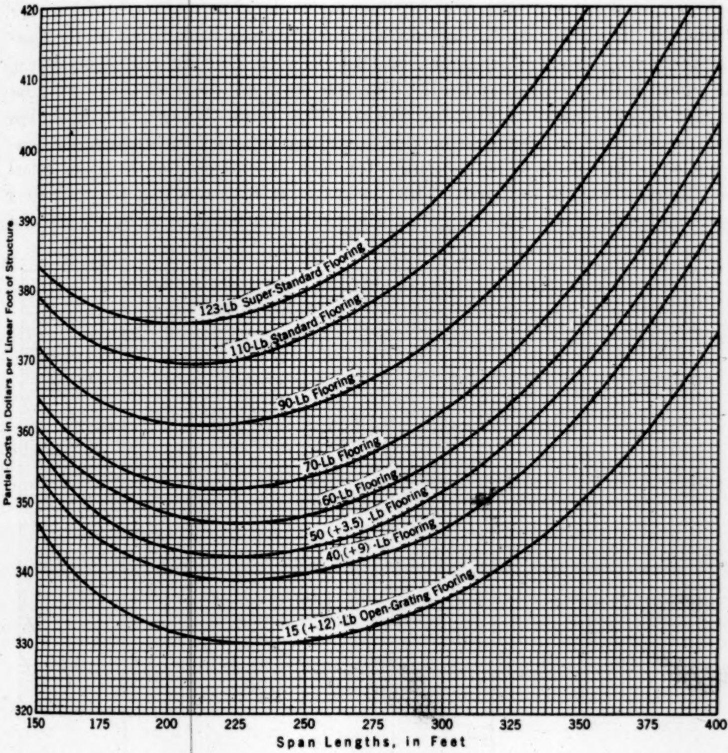

FIG. 1.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF CARBON STEEL; 45-FOOT CLEAR ROADWAY

BASIC ASSUMPTIONS

A series of solid floorings having weights per square foot of floor equal to 123, 110, 90, 70, 60, 50, and 40 lb, as well as an open-grate flooring computed for 15 lb per sq ft, plus an allowance of 12 lb per sq ft for small I-beam cross-girders, was assumed; and, for each one of the series, an arbitrary (but logical) cost per square foot was adopted, including royalty, these costs generally increasing as the weight of floor-slab diminishes.

Next, cost curves were plotted to cover the substructure, the superstructure metal work contained in the floor system proper (on the basis of 5-ft stringer spacing), the lateral system, and the trusses (excluding the metal on piers and in the anchorages) for both simple-truss spans and cantilever bridges, in both carbon steel and silicon steel, and for both wide roadways and narrow roadways. These curves do not contain the costs per linear foot of the flooring, the metal in extra stringers, or that between flooring and floor system, the guard-rails, or the hand-rails; but the costs of these enumerated items (except only the hand-rails) are given in tables, using the assumed unit prices that are adopted in the text for this investigation. In the future, the foregoing costs will need to be computed for each special case as it arises before the diagrams can be utilized. This program, at first reading, may appear a bit complicated; but the examples, given hereinafter, for utilizing the cost curves will make the procedure perfectly clear.

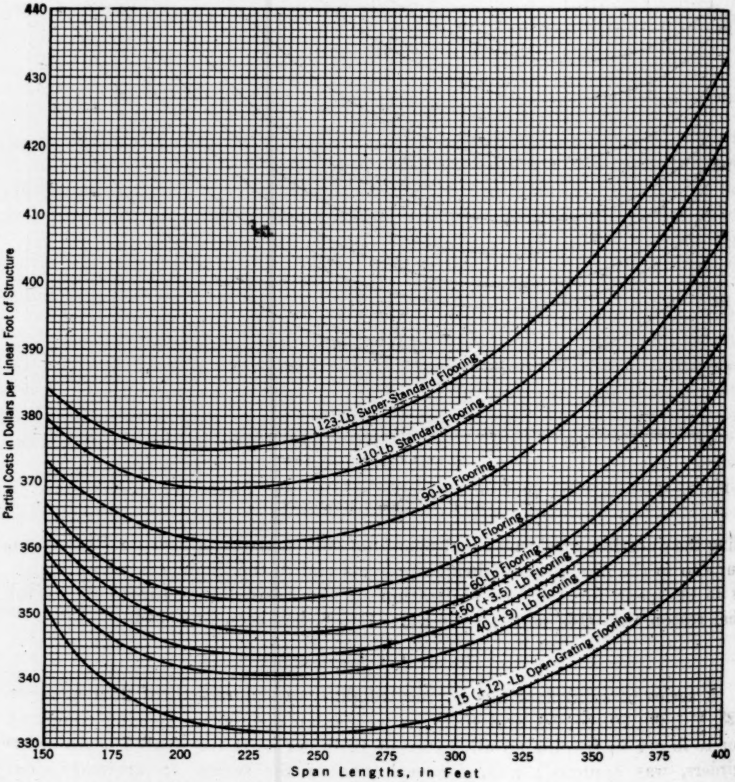

FIG. 2.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF SILICON STEEL; 45-FOOT CLEAR ROADWAY; SPANS, 150 FEET TO 400 FEET.

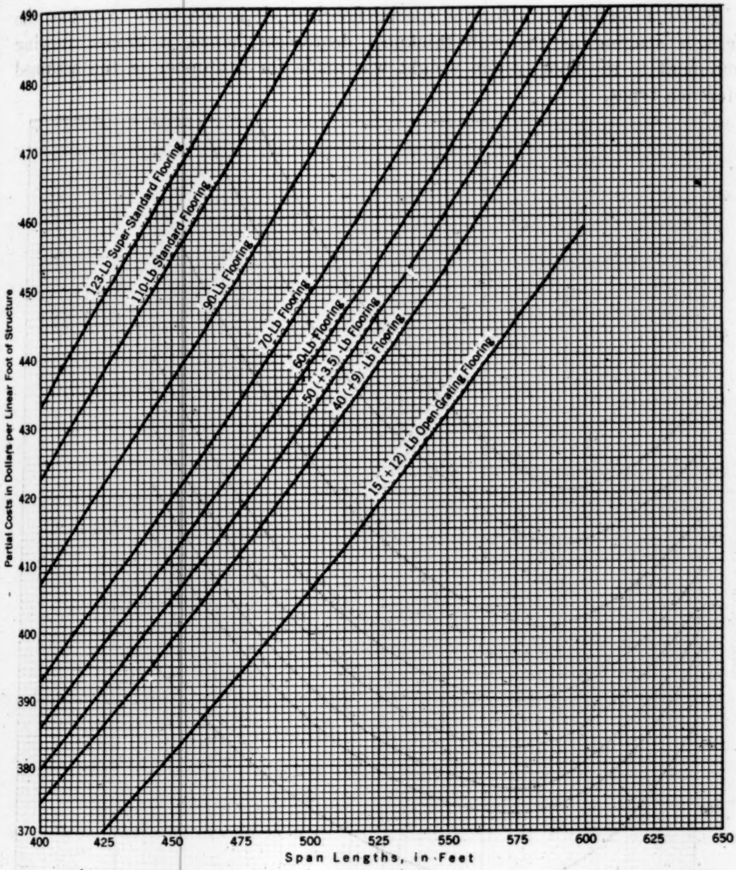

FIG. 3.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF SILICON STEEL; 45-FOOT CLEAR ROADWAY; SPANS, 400 FEET TO 650 FEET.

Because of its common use, a 110-lb, 9-in. slab floor of ordinary reinforced concrete, consisting of an 8-in. structural slab with its thickness increased 1 in. for wear, has been selected as the "Standard" type of non-patented flooring. The 123-lb flooring, designated as "Super-Standard", consists of an 8-in., reinforced concrete slab, covered with a 2-in. thickness of asphalt paving. For both these types, the stringer spacing was assumed to be 5 ft.

The 90-lb flooring represents a 7-in., concrete slab reinforced with trusses of welded-bar or other rigid construction, also carried by stringers spaced 5 ft on centers. This thickness includes 1 in. of wearing surface.

Below a certain limit for the special floorings, it is necessary to reduce the stringer spacing as the slab thickness decreases; hence, a proper varying increment to the floor-system weight was made for a number of the assumed reference types.

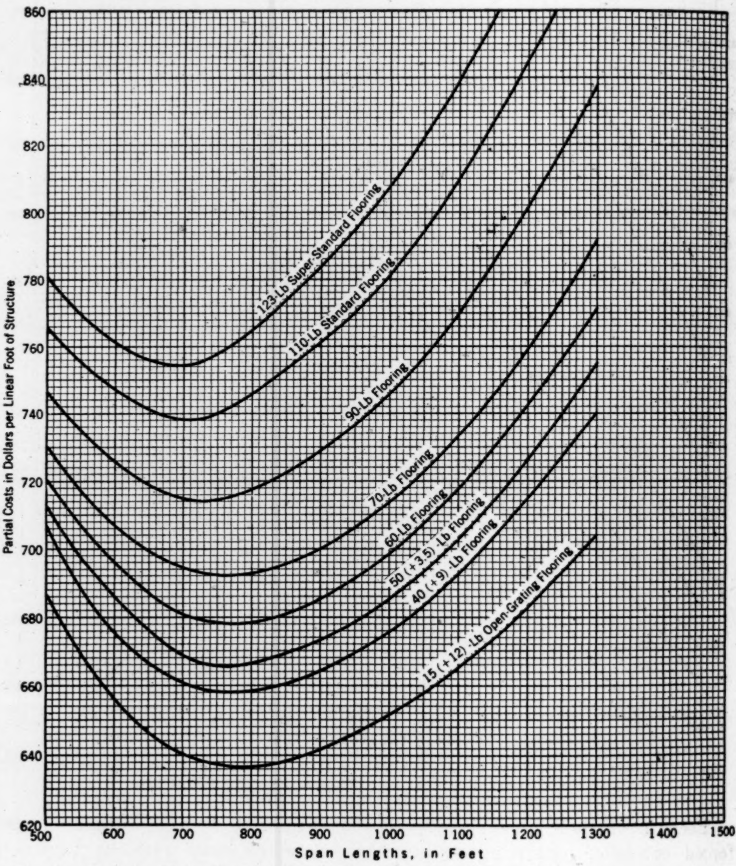

FIG. 4.—PARTIAL UNIT COST OF TYPE *A*, CANTILEVER HIGHWAY BRIDGES OF SILICON STEEL; 45-FOOT CLEAR ROADWAY.

The open-grate flooring of this comparative series was based on using $\frac{3}{16}$-in. metal throughout, but it is better practice to make the straight (or carrying) bars $\frac{1}{4}$ in. thick. This would add 2 lb per sq ft to the weight of the floor, but would permit a saving of 1 lb per sq ft (through slightly wider spacing) in the weight of the small transverse I-beams, making a net increase of 1 lb of metal per sq ft. Consequently, if the heavier carrying bars are used, it will be necessary to allow a rebate of 4 cts per sq ft of floor, but,

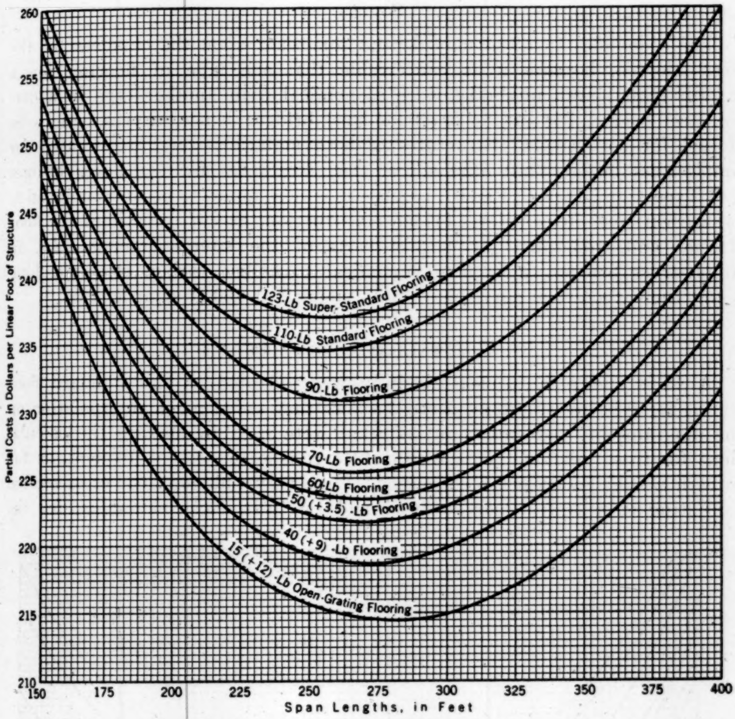

FIG. 5.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF CARBON STEEL; 20-FOOT CLEAR ROADWAY.

on the other hand, to provide for the increased cost of the structure due to the extra load of 1 lb per sq ft. In Table 1 are recorded full data concerning these eight comparable floorings.

TABLE 1.—DATA CONCERNING COMPARABLE FLOOR TYPES

Item No.	Type	Total weight of floor, in pounds per square foot	Cost in place per square foot	Allowance included in cost for extra floor metal as compared with the standard, Item No. 2
1	Super-standard flooring.....	123	$1.00	None
2	Standard flooring..........	110	0.80	None
3	90-lb flooring...	90	1.00	None
4	70-lb flooring...	70	1.50	None
5	60-lb flooring...	60	1.40	None
6	50-lb flooring...	50	$1.30 + 0.18 = $1.48	3.5 lb. @ 5 cts = $0.18
7	40-lb flooring...	40	1.40 + 0.36 = 1.76	9 lb. @ 4 cts = 0.36
8	Open-grate flooring......	15	1.40 + 0.48 = 1.88	12 lb. @ 4 cts = 0.48

STEELS

The economics involved may depend somewhat upon the character of the steel adopted, because it is conceivable that one type of flooring for a certain span length might be more economical than another type in a carbon-steel bridge, but not in a silicon-steel bridge; hence, curves had to be plotted for both steels. Structures of both materials were investigated for simple-truss bridges, but only silicon-steel structures for cantilever bridges (see Type *A* and Type *C*, Fig. 9), because it is now found to be uneconomical to use carbon steel in cantilever-bridge construction, except sometimes for floor systems and, generally, for certain parts of the lateral bracing. As, in simple-truss bridges, it is not economical to utilize carbon steel for long spans, the carbon-steel curves have been stopped at 400-ft span lengths.

ROADWAYS AND SIDEWALKS

A 45-ft and a 20-ft clear roadway were adopted as the standard floor widths for this investigation, partly because they saved much interpolation on the diagrams of "percentage ratios" that were used in making the calculations for truss weights. This width of 45 ft is practically equivalent, as far as both weight and cost are concerned, to the very common floor cross-section consisting of a 40-ft, clear roadway and two 5-ft, clear sidewalks, for the

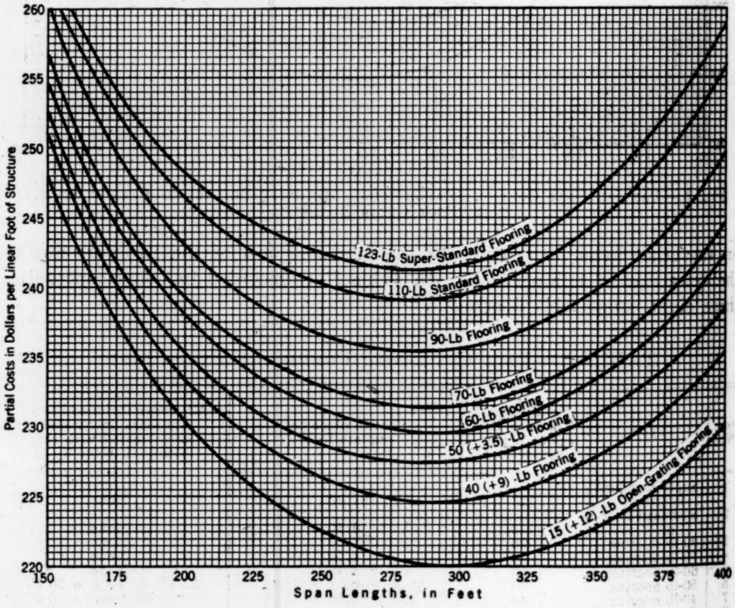

FIG. 6.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF SILICON STEEL; 20-FOOT CLEAR ROADWAY; SPANS, 150 FEET TO 400 FEET.

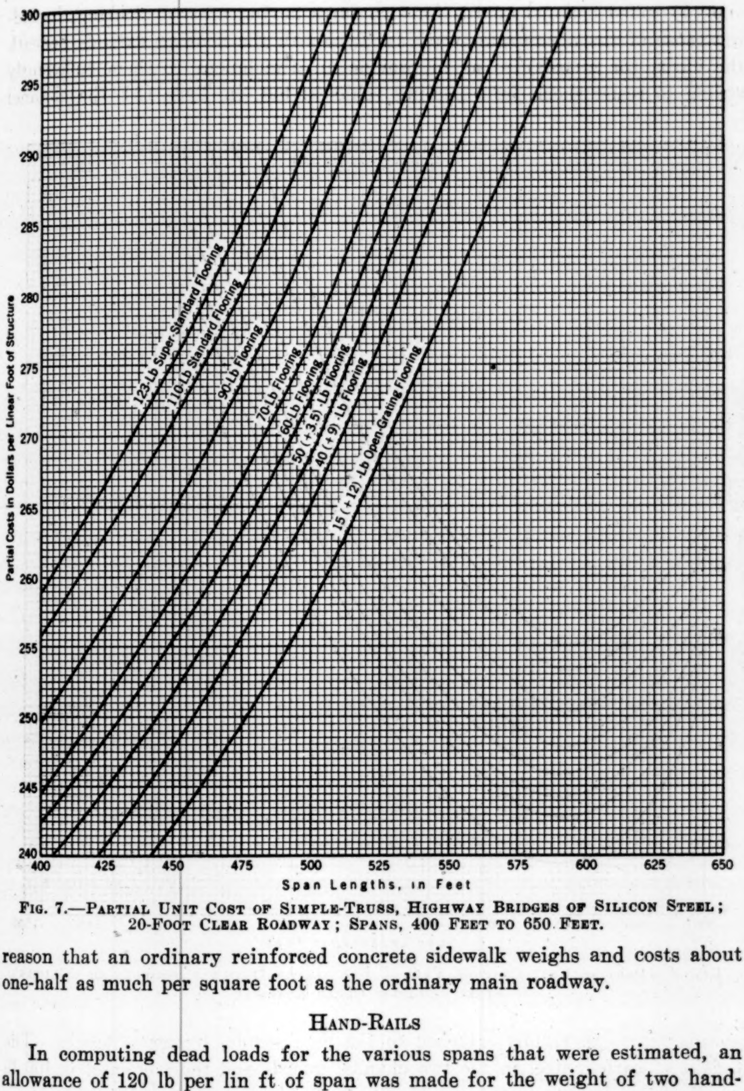

FIG. 7.—PARTIAL UNIT COST OF SIMPLE-TRUSS, HIGHWAY BRIDGES OF SILICON STEEL; 20-FOOT CLEAR ROADWAY; SPANS, 400 FEET TO 650 FEET.

reason that an ordinary reinforced concrete sidewalk weighs and costs about one-half as much per square foot as the ordinary main roadway.

HAND-RAILS

In computing dead loads for the various spans that were estimated, an allowance of 120 lb per lin ft of span was made for the weight of two hand-rails, but their cost has been (and in the future use of this paper is to be) ignored, as it is common to all the competing structures investigated.

GUARD-RAILS

Two types of guard-rails have been adopted for this investigation: (*a*) 12 by 12-in. curbs of reinforced concrete for structures with solid floors;

and (*b*) rolled channel guards for structures having all-steel flooring, including those of the open-grate type. In Type (*a*), the flooring extends beneath the curbs (or guards) so as to provide an attachment to them sufficiently strong to resist shock from passing vehicles; but, in Type (*b*), the channel guards are to be rigidly attached to the floor system by metal braces. The weight of carbon steel in the two channel guards and their bracing is 100 lb per lin ft, and the cost, in place, is $4 per lin ft.

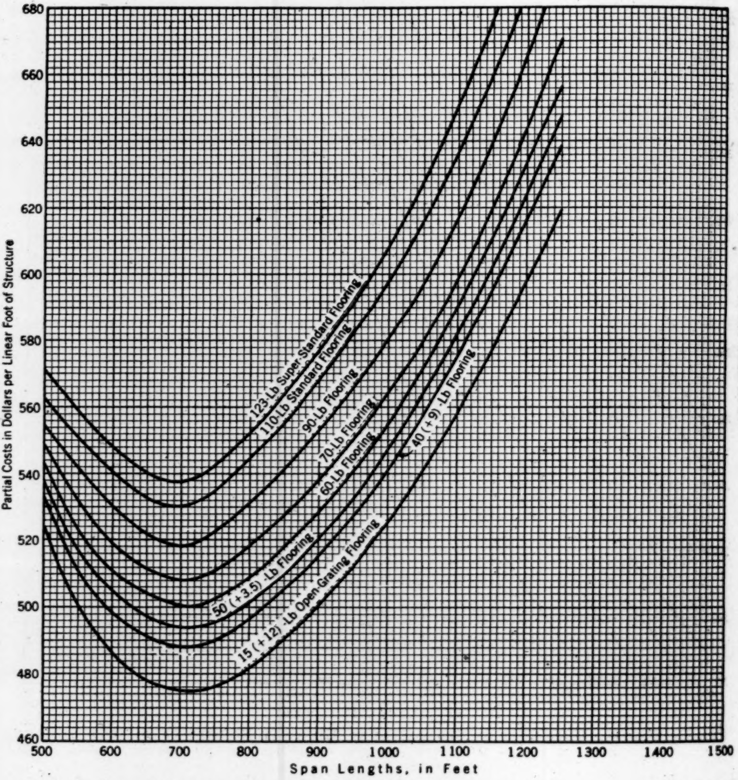

FIG. 8.—PARTIAL UNIT COST OF TYPE *A* CANTILEVER HIGHWAY BRIDGES OF SILICON STEEL; 20-FOOT CLEAR ROADWAY.

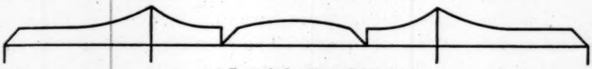
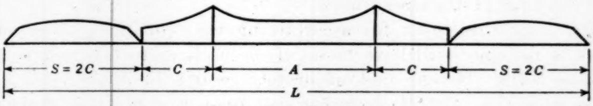
The cost per linear foot of structure for the two reinforced concrete guards and their supporting base is $2 for the 2 cu ft of concrete in the curbs, plus the value of 2 sq ft of the flooring. It is self-evident that there is no need for extending the flooring outside the inner faces of the channel guard-rails.

SPECIFICATIONS

The standard specifications that were used for making the computations are those now current, involving basic tensile unit stresses of 18 000 lb per sq in. for carbon steel and 24 000 lb per sq in. for silicon steel.



(a) Type *A*, Cantilever Bridge



(b) Type *C*, Cantilever Bridge

FIG. 9.

Although all the data in this paper are based on the usual standard (H-20) live loading, the general economic conclusions will apply quite closely to structures designed for lighter live loadings. For the usual H-15 loading, for instance, the 5-ft stringer spacing could be increased for all types of floor, or it could be kept unchanged and thinner floor-slabs utilized. In general, the percentage saving resulting from the use of the lighter floorings will be found a little less for the lighter live loads than for the H-20 loading.

DEAD LOAD REDUCTION EFFECT ON PIERS

Any reduction in dead load saves money, not only on the superstructure, but usually also on the substructure because it is the sizes of shoe-plates that dictate both the width and the length of the pier tops; hence, it was necessary to include the cost of the substructure in making the comparative curves of costs per linear foot of bridge.

LOCATION EFFECT

As bridge costs differ somewhat in various parts of the United States, it was considered advisable to select a particular locality for the comparison; and Kansas City, Mo., was chosen as being centrally located.

ADDITIONAL METAL FOR SUPPORTING THIN FLOORINGS

Thin floorings may require more closely spaced supports than the "standard" flooring (Item No. 2, Table 1). There are two ways of accomplishing this requirement—either by inserting additional stringers, or by adhering to the 5-ft spacing that is used with the "standard" flooring and crossing the stringers with small **I**-beams, spaced as far apart as the strength and the rigidity of the flooring under consideration will permit. The second method is the better one from the point of view of stiffness; and it is sometimes also the more economical.

As none of the usual floorings less than 3 in. in thickness will permit of a support-spacing in excess of 3 ft, and as the cross-**I**-beam construction is usually so much more satisfactory, the writer concluded to utilize it for such thin floorings. For floorings weighing 60 lb per sq ft, or more, or for those $3\frac{1}{2}$ in., or more, thick, he assumed them to be able to carry properly over a 5-ft spacing. For thin floorings ranging from 3 to $3\frac{1}{2}$ in., he adopted a stringer spacing of 4 ft; and for all still thinner floorings the small transverse I-beams were used, their spacing being dependent upon the strength and rigidity of the floorings. The greatest, safe, usable, span length of any flooring is so difficult to compute that tests to destruction may be needed to determine its strength.

Before using this paper for ascertaining the economics of any particular flooring, the designer will have to satisfy himself as to this safe span length, l (less than 5 ft). He can find, accurately enough for his purpose, the corresponding excess weight of floor metal, e, per square foot of floor by the formula,

$$e = 3.5\ (5 - l) \quad \text{..........................} \quad (1)$$

For instance, if $l = 4$ ft, e will be 3.5 lb.

TRUSSES

The truss weights were readily obtained by a method presented[3] by the writer in 1935. In Type *A* cantilever bridges[3] they were the properly adjusted average weights for the entire structure, namely, one suspended span, two cantilever arms, and two anchor arms, the metal in anchorages and on piers being omitted

CORRECTION FOR EFFECT OF WIND LOAD

It was anticipated originally that the computed truss weights would require correction to cover the effect of wind loading upon the sectional areas of certain bottom-chord members for all the various floorings, except the "standard" type, in which this effect had already been included. Such was found not to be the case for the simple-truss spans with the 45-ft, clear roadway; but it held true for the simple-truss spans with the 20-ft, clear roadway, and for all cantilever spans.

These corrections were determined by reference to several actual bridges designed with "standard' floorings, in which the wind loads had increased some of the bottom-chord sections. The weight of extra metal that would be required to care for the wind loading, if the dead load were reduced by using the lightest of all the floorings, was also computed. Cases of both wide and narrow roadways, involving both carbon steel and silicon steel, were selected; and enough of them were introduced to render this method of correction for wind loading perfectly satisfactory. The corrections for intermediate floorings were interpolated by proportionate weights per square foot of flooring.

---

[3] "Weights of Metal in Steel Trusses", *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1.

NARROW ROADWAY

Were it not for the aforementioned feature of correction for the effects of wind loading, the comparative economics of the various types of flooring might have been assumed as constant for all widths of roadway; but, unfortunately, this feature is much more potent for narrow roadways than for wide ones; hence, the writer deemed it advisable to prepare the curves in Figs. 5 to 8, inclusive, in order to cover highway bridges of 20-ft clear roadway. The methods of calculation used were the same as those for the structures of the 45-ft clear roadway, except only that carbon-steel floor systems were adopted in otherwise silicon-steel bridges for Figs. 6 and 7 and carbon-steel stringers with silicon-steel cross-girders for Fig. 8, and that the pound prices for metal erected were duly adjusted for the mixed steels. Proper cognizance was taken of the increased weights of metal in floor systems due to the necessary spreading of trusses in long-span, narrow-roadway bridges, in order to comply with standard engineering practice.

UNIT PRICES OF STEEL ERECTED

The following unit prices of steel, erected, were adopted as representing the average current values at Kansas City, including a proper profit to the contractor, for bridges with the "standard" flooring:

Simple-truss structures of carbon steel........	5 cts per lb
Simple-truss structures of silicon steel........	6 cts per lb
Cantilever structures of silicon steel..........	7 cts per lb

For the mixed steels used in computing the curves of Figs. 3 and 4, the average unit prices for bridges with the "standard" flooring ranged uniformly from 5.4 cts at 150-ft spans, to 5.7 cts at 600-ft spans; and for those used in computing the curves of Fig. 5, they ranged from 6.65 cts at 500-ft main openings to 6.85 cts at 1 200-ft main openings.

For structures with decks lighter than the "standard," a correction in the unit prices of the metal work was made, because, as the weight of metal in a structure is reduced, its pound price, erected, will increase. This correction was effected by means of the formula,

$$C' = \frac{C}{4}\left(3 + \frac{w}{w'}\right) \text{ ....(2)}$$

in which w = the weight of metal, in pounds per linear foot, in the bridge with the heavier deck; w' = the weight of metal, in pounds per linear foot, in the bridge with the lighter deck; C = the unit cost of metal, erected, in the bridge with the heavier deck; and C' = the unit price of metal, erected, in the bridge with the lighter deck.

SUBSTRUCTURES

In determining the costs for substructures, it seemed desirable to make a distinction between the assumed profiles of crossings for simple-truss structures and those for cantilever structures. Generally, the grade line is lower in the former than in the latter, and the depths below the water-line of the pier foundations are often less. For the simple-truss bridges, the height of the shafts was taken at 42 ft, and the height of the pneumatic bases at 50 ft, whereas, for the cantilever bridges, both the shafts and the bases were assumed to be 84 ft high.

The all-around batter adopted for all piers was $\frac{1}{2}$ in. to the foot. Dumbbell shafts, as illustrated in plan by Fig. 10, were adopted for all cases, because of their economy in materials and cost. For the simple-truss bridges, with 45-ft roadways, two separate bases were assumed; but for the bridges with 20-ft roadways, and for all cantilever structures, single bases were adopted. The reason for the single bases in narrow structures is that there would probably be no great pecuniary advantage in dividing them; and their use in cantilevers is generally called for because of location over navigable streams where the bed-rock is deep, and where, consequently, the sinking of small bases would be expensive per unit of volume.

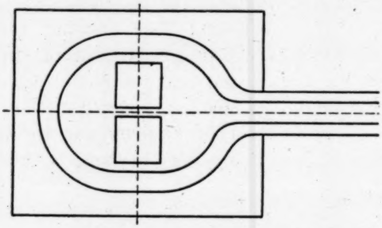


FIG. 10.—PLAN OF PIER TOP.

In computing the costs per linear foot for the substructures of simple-truss bridges, the total value of one pier was estimated, and the amount was divided by the distance between pier centers; whereas in the case of cantilever bridges, the total value of a main pier was divided by one-half the length of the main opening plus one-half that of one anchor arm. This method assumes that one-half of each anchor arm pertains entirely to its anchor pier. As the design for any anchorage varies greatly with the foundation conditions, it is not advisable to assume the latter, but, instead, to designate the cost per linear foot of the substructure the amount computed from the value of one main pier, as previously described. If this is not strictly exact, no harm can be done, because all the competitive costs per linear foot are affected alike.

UNIT PRICES FOR SUBSTRUCTURE

For the masses of materials in the shafts and walls and in the pneumatic bases of piers, the following unit prices were adopted for structures with the "standard" flooring:

Simple-Truss Structures:	
Shafts and walls	$15 per cu yd
Bases	$22 per cu yd
Cantilever Structures:	
Shafts and walls	$17 per cu yd
Bases	$25 per cu yd

For structures with decks lighter than those of the "standard" flooring, a correction in substructure unit prices was applied, as in the case of superstructure metal, because, as the size of the pier decreases, the unit prices of shafts, wall, and bases will increase. This correction was made by means of the formula:

$$C' = \frac{C}{4}\left(3 + \frac{V}{V'}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which V = total volume of shafts, wall, and base or bases, in pier with heavier deck; V' = total volume of shafts, wall, and base or bases, in pier with lighter deck; C = one of the substructure unit prices for pier with heavier deck; and, C' = the corresponding substructure unit price for pier with lighter deck.

In respect to the application of the unit-price generic factor,

$$C' = \frac{C}{4}\left(3 + r\right), \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

each of the sets of curves in this paper, was treated as an independent entity; in other words, these factors do not function from diagram to diagram or from span length to span length, but only, in each diagram and for each span length, between the "standard" flooring and the other floorings.

PIER DESIGNING

In pier designing, all steel pedestals were made square; and, in simple-truss structures, 6 in. clear were left between them. In these designs from the edge of any pedestal base-plate to the edge of the masonry, a minimum distance of 9 in. was allowed. The heavier of the two similar piers was first designed and estimated, and then the dimensions were reduced (always exactly and in like manner) to agree with the lighter superimposed load on the pedestal or pedestals. The interpolation of pier costs for the other types of flooring was done with due reference to the superimposed loads and to the varying unit-prices of materials in place.

For convenience, all piers were assumed to rest on solid rock. Had pile foundations been adopted, a still more economic showing would have been indicated for the light floorings. In computing volumes of shafts, the prismoidal-formula method was used invariably; but for the walls, the simpler method of averaging end areas was deemed to be sufficiently accurate. The permissible load on concrete under pedestals was taken at 600 lb per sq in., according to the latest standard specifications of the American Association of State Highway Officials.

EFFECT OF PILE FOUNDATIONS

It has been stated that, had pile foundations been adopted instead of those of solid rock, a better showing would have been made for the lighter floorings. For example, consider a foundation with 100-ft, large-diameter, timber, friction piles, embedded 10 ft in the concrete. A bearing capacity of 45 tons per pile was assumed, the cost per linear foot of pile in place below the base being $1.00, and the cost per cubic yard of the mass of base (placed by a steel sheet-pile coffer-dam) being $20.00. The costs of the two piers thus computed per linear foot of span, for the "standard" and the open-grate floorings, are $98.44 and $82.20, respectively, indicating an advantage of 16.5% in the substructure for the lightest flooring when compared with the "standard." The longer the span the greater would be this percentage of advantage. The corresponding percentage for piers resting on bed-rock is 14.5%, showing that the lightest flooring is only a little, if any, more economical with pile foundations than with rock foundations.

Effect of Excess Weights in Floor Systems

Before proceeding to show how to use the cost curves for actual cases of competition, it is necessary to indicate how to deal with any excess weight of metal per linear foot of span, as compared with the allowance therefor recorded in Table 1. If a competitor has a flooring so thin that it is not strong enough properly to carry over a 5-ft stringer-spacing, it will be necessary, as previously indicated, to put in either additional stringers, or small transverse **I**-beams, thus adding a number of pounds (*n*) per linear foot to the total load to be carried. It is then necessary merely to add to the cost of the floor the product of *n* by the pound price of the metal erected, and to include the extra weight of the metal per square foot of floor when entering the various diagrams

Diagrams of Partial Costs

In the curves accompanying this paper are recorded the computed partial costs (including substructure, trusses, lateral systems, and floor system) per linear foot of structure, for the various types of bridges and the floorings listed in Table 1. As can be seen from these diagrams, the simple-truss spans vary from 150 ft to 600 ft in length, and the Type *A* cantilever spans from 500 ft to 1 200 ft of main opening, all measured from center to center of piers.

On the lowest three curves of each diagram there is noted the weight of extra floor metal resulting from close stringer spacing or small cross-beams, as assumed in Table 1, as well as the weights of the flooring itself, because the trusses and substructure were designed to carry the weight of this extra metal These three curves, therefore, should be considered as representing floors weighing 53.5 lb, 49 lb, and 27 lb per sq ft.

Type C Cantilevers.—The curves for the Type *A* cantilever bridges can be used for Type *C* cantilever bridges by multiplying the main opening of the latter by 1.43.

Method of Computing the Total Costs of a Structure

References have been made in the text to the fact that the several diagrams record partial costs of bridges per linear foot of structure, and it was indicated that the curves covered only the cost of the substructure and that of the trusses, lateral system, and floor system upon the basis of a 5-ft spacing of floor stringers. In order to find the total cost per linear foot for any case, there must be added to the data given in the diagram the costs per linear foot for: (*a*) The flooring between curbs; (*b*) any extra stringers, at the unit price, erected, of the metal for the entire bridge; or, (*c*) the small cross-girders that rest on the stringers, worth in place only 4 cts per lb; and, (*d*) the steel guard-rails or the reinforced concrete curbs, as the case may be.

TABLE 2.—ADDITIONAL COSTS OF STRUCTURES, SUPPLEMENTING DATA FROM THE CURVES, FOR FINDING TOTAL UNIT COSTS

Types of flooring	Costs of flooring per linear foot of bridge	Costs per linear foot of extra metal in floor system	Costs per linear foot of curbs or guard-rails	Summation, giving total extra costs per linear foot to add to diagram, readings
(*a*) DATA TO SUPPLEMENT FIGS. 1 TO 4, INCLUSIVE, FOR WIDE HIGHWAY BRIDGES				
Super-standard....	45 ft. @ $1.00 = $45.00	None	$2.00 + $2.00 = $4.00	$49.00
Standard.........	45 ft. @ 80 cts. = $36.00	None	1.60 + 2.00 = 3.60	39.60
90-lb............	45 ft. @ $1.00 = $45.00	None	2.00 + 2.00 = 4.00	49.00
70-lb............	45 ft. @ $1.50 = $67.50	None	3.00 + 2.00 = 5.00	72.50
60-lb............	45 ft. @ $1.40 = $63.00	None	2.80 + 2.00 = 4.80	67.80
50-lb in carbon-steel bridges....	45 ft. @ $1.30 = $58.50	45 ft. @ 18 cts. = $8.10	2.60 + 2.00 = 4.60	71.20
50-lb in simple-truss bridges of silicon steel	45 ft. @ $1.30 = $58.50	45 ft. @ 21 cts. = $9.45	2.60 + 2.00 = 4.60	72.55
50-lb in cantilever bridges of silicon steel	45 ft. @ $1.30 = $58.50	45 ft. @ 24.5 cts. = $11.03	2.60 + 2.00 = 4.60	74.13
40-lb............	45 ft. @ $1.40 = $63.00	45 ft. @ 36 cts. = $16.20	4.00	83.20
Open-grating.....	45 ft. @ $1.40 = $63.00	45 ft. @ 48 cts. = $21.60	4.00	88.60
(*b*) DATA TO SUPPLEMENT FIGS. 5 TO 8, INCLUSIVE, FOR NARROW HIGHWAY BRIDGES				
Super-standard....	20 ft. @ $1.00 = $20.00	None	$2.00 + $2.00 = $4.00	$24.00
Standard.........	20 ft. @ 80 cts. = $16.00	None	1.60 + 2.00 = 3.60	19.60
90-lb............	20 ft. @ $1.00 = $20.00	None	2.00 + 2.00 = 4.00	24.00
70-lb............	20 ft. @ $1.50 = $30.00	None	3.00 + 2.00 = 5.00	35.00
60-lb............	20 ft. @ $1.40 = $28.00	None	2.80 + 2.00 = 4.80	32.80
50-lb in carbon-steel bridges....	20 ft. @ $1.30 = $26.00	20 ft. @ 18 cts. = $3.60	2.60 + 2.00 = 4.60	34.20
50-lb in simple-truss bridges of silicon steel	20 ft. @ $1.30 = $26.00	20 ft. @ 21 cts. = $4.20	2.60 + 2.00 = 4.60	34.80
50-lb in cantilever bridges of silicon steel	20 ft. @ $1.30 = $26.00	20 ft. @ 24.5 cts. = 4.90	2.60 + 2.00 = 4.60	35.50
40-lb............	20 ft. @ $1.40 = $28.00	20 ft. @ 36 cts. = $7.20	4.00	39.20
Open-grating.....	20 ft. @ $1.40 = $28.00	20 ft. @ 48 cts. = $9.60	4.00	41.60

These additional costs in wide highway bridges for the flooring types and the unit prices given in Table 1 are presented in Table 2(*a*). These data will supplement Figs. 1 to 4, inclusive, for finding the total unit costs of wide highway bridges. The corresponding data for narrow highway bridges, to supplement Figs. 5 to 8, inclusive, are given in Table 2(*b*).

How to Use the Cost Curves

Assume, for example, that an engineer is contemplating the building of a four-lane, Type *A*, cantilever bridge, having a main opening of 750 ft, and two 5-ft sidewalks, and that he intends using a solid flooring. Two types of floor have been shown him, one by Mr. Smith and another by Mr. Jones. Either type would be satisfactory; hence, his choice is merely a matter of economics.

The flooring offered by Mr. Smith is 3 in. thick, weighs 58 lb per sq ft, and costs $1.23 per sq ft in place; but it has a superior limit of only 4 ft between supporting girders, necessitating 3.5 lb of extra metal per square foot of floor, worth 7 cts per lb in place.

The flooring shown by Mr. Jones, is $2\frac{1}{2}$ in. thick, weighs 45 lb per sq ft, and costs $1.18 per sq ft in place; but it requires, for a stringer spacing of 5 ft, small transverse I-beams, which he justly claims will weigh only 8 lb, and will cost only 32 cts per sq ft of floor.

Mr. Smith's Case.—Turning to Fig. 4, and interpolating for 58 + 3.5 = 61.5-lb flooring, the "partial cost" indicated is $680 per lin ft of bridge. The remaining cost per linear foot is found thus:

Flooring, 45 ft @ $1.23	$55.35
Extra metal in floor system, 45 × 3.5 = 158 lb worth 7 cts per lb, or	11.06
Curb supports, 2 × $1.23 = $2.46. Adding $2.00 for curbs makes	4.46
Summation	$70.87
Plus partial cost from Fig. 4	680.00
Total cost of bridge with Mr. Smith's flooring	$750.87

Mr. Jones' Case.—Turning to Fig. 4, and interpolating for 45 + 8 = 53-lb flooring, the "partial cost" indicated is $666 per lin. ft. The remaining cost per linear foot is found thus:

Flooring, 45 ft @ $1.18	$53.10
Extra metal in floor system, 45 × 8 = 360 lb worth 4 cts per lb, or	14.40
Steel guard-rails, 100 lb @ 4 cts	4.40
Summation	$71.50
Plus partial cost from Fig. 4	666.00
Total cost of bridge with Mr. Jones' flooring	$737.50
Difference in favor of Mr. Jones = $750.87 − $737.50 =	$13.37

To assume another case—a succession of wide, simple-truss, carbon-steel spans of 250 ft each: Mr. Brown thinks he can compete with the standard flooring by quoting a price of $1.30 per sq ft of floor for his type of flooring, which is 3 in. thick and weighs 50 lb per sq ft. It requires a 4-ft spacing of stringers, necessitating 3.5 lb per sq ft of extra metal for stringers, worth 5 cts per lb in place—the same as the 50-lb flooring in Table 1.

Turning to Fig. 1, the "partial cost" for 50 + 3.5 = 53.5-lb flooring is found to be $343.50. The remaining cost per linear foot is found thus:

Flooring, 45 ft @ $1.30	$58.50
Extra metal, 45 × 3.5 = 158 lb @ 5 cts	7.90
Curb supports, 2 × 1.30 = $2.60. Adding $2.00 for curbs makes	4.60
Summation	$71.00
Plus partial cost from Fig. 1	343.50
Total cost with Mr. Brown's flooring	$414.50
For the "standard" flooring, Fig. 1 indicates a partial cost of	$373.20
Table 2(*a*) gives a remaining cost as	39.60
Plus the total cost with "standard" flooring is	$412.80

Mr. Brown, consequently, does not secure the contract.

The following is an illustration of how to apply the diagrams to a comparison of the economics of an open-grate flooring and the "standard" flooring: An engineer has a 4-lane, simple-truss, silicon-steel, highway bridge, with a succession of 380-ft spans and double, 5-ft sidewalks, to design and build, and desires to know what percentage of saving in cost can be obtained by means of an open-grate flooring which has the longitudinal pieces, $\frac{1}{4}$ in. thick. The best quotation he can secure for the flooring is $1.50 per sq ft in place. The open-grate flooring, of course, will be the criterion to use; but, as previously indicated, the thickness of the longitudinal pieces adopted for this type in Table 1 was $\frac{3}{16}$ in. The increased thickness adds 2 lb per sq ft of floor to the dead load, but reduces the weight of the special cross-girders from 12 lb to 11 lb per sq. ft, thus making the net increase in total load, 1 lb per sq ft, or 45 lb per lin. ft of span. Turning to Fig. 2 the "partial cost" in pounds per linear foot, is found to be as follows:

Standard flooring	$411.00
Open-grate flooring (for 17 + 11 = 28 lb)	353.60
Table 2(*a*) gives for the remaining cost of the standard flooring	39.60
Making the total cost for the bridge with standard flooring, $411.00 + $39.60	$450.60

For the open-grate structure the additional cost is found thus:

Flooring, 45 × 1.50	$67.50
Extra metal in floor system, 11 × 45 = 495 lb @ 4 cts	19.80
Guard-rails	4.00
Summation	$91.30
Plus partial cost from Fig. 2	353.60
Total	$444.90

The ratio of costs, therefore, will be $\frac{\$444.9}{\$450.6} = 0.987$. Hence, the saving will be 1.3 per cent.

MOVABLE SPANS

This investigation has thus far ignored an important economic application of light floorings, namely, their use in vertical-lift and bascule bridges. In these cases, regardless of span length, there is a decided saving of money in adopting any of the light floorings, especially an open-grate flooring, because the economy involved is not confined (as in fixed spans) to the floor system and the trusses, but extends to the cables with their connections, the counterweights, the sheaves with their bearings, the towers, the entire operating machinery in vertical-lift bridges and bascules, and to numerous other parts of bascule bridges—all in addition to the saving in cost of substructure.

In the past, almost all bascule spans have been designed with light flooring, first of timber (which is most objectionable because of fire risk) and, later, of some patented type of thin flooring; but many vertical-lift spans have had ordinary flooring of reinforced concrete; and the weight of this flooring constitutes a considerable portion of the total load to be raised and lowered.

The open-grate flooring has an additional advantage for bascule spans, shared by no other type of flooring: When the span is being raised or lowered, the force of the wind blowing through the grating largely reduces the pressure against the floor, thus lessening materially, under certain extreme conditions of operation, the quantity of power required to raise or to lower the moving leaf.

The open-grate flooring has a characteristic that is of considerable economic importance in vertical-lift bridges—it does not have a tendency to collect snow or ice. Therefore, the customary excess-load allowance for snow or ice of 5 lb per sq ft of floor in such structures may safely be reduced, thus effecting quite a saving in total cost of structure and of the operating machinery, in addition, of course, to the numerous economies from the reduced weight of the flooring itself.

The combination of all these savings by the open-grate flooring on both vertical-lift and bascule spans is so large, in comparison with the ordinary reinforced concrete deck, as always greatly to overcome the handicap of the excess unit-price of the lighter flooring. At present (1937) it is not worth while to attempt to investigate the comparative economics of the various light floorings on movable spans; but at some time in the future it might prove otherwise.

TRESTLE BRIDGES

In view of the present, very intensive introduction of elevated highway structures to relieve the congestion of traffic in metropolitan centers, the writer has been urged to treat the economy of floors on such structures.

In general, such structures are composed essentially of short spans, and are similar in layout to elevated railways in cities and to ordinary trestles. In such cases there is absolutely no economic advantage in lightening the floor by increasing, materially, its cost per square foot. The usual thick, reinforced concrete flooring, therefore, is the best type to adopt for both economy and rigidity, providing the matter of lateral skidding is ignored; but should such structures contain spans exceeding 250 ft in length, a lighter flooring might be economical on these longer spans.

SUSPENSION BRIDGES

The economics of the various types of flooring for suspension bridges may be stated in a very few words—the lighter the flooring the less will be the first cost of the structure, and, therefore, the open-grate type would seem to be called for in all cases; but sometimes the designer may desire to rely upon continuity in the flooring for lateral rigidity, because the usual narrow suspension bridge is unquestionably lacking in that desideratum. In such a case, it might be well to use a thin, solid flooring; but the writer's preference would be to adopt the open grate and provide a rigid, substantial lateral system near the plane of the deck.

A study of Figs. 4 and 8, in conjunction with Table 2, should convince any one that heavy floorings are always uneconomical in cantilever bridges, and that the open-grate flooring is specially economical for this type. It is conceded that a thick, solid flooring on the anchor arms would reduce the uplifts at the anchorages, and thus effect a saving in the truss weights of cantilever bridges, as well as in the cost of the flooring itself; but such a saving would not be as great as the gain from the reduced dead loads on the entire main span caused by the open-grate, which reduction affects favorably all the trusses in the suspended span, the cantilever arms, and the anchor arms. It is true that the open grating could be used on the main span, and the heavy flooring on the anchor arms; but the hybrid deck thus produced would be objectionable from the æsthetic viewpoint, and, possibly, also for other reasons.

WARNING

Some one may claim that a fundamental change in the governing unit prices for materials and labor in connection with bridge building will render null and void the service of the cost-curve diagrams; but such is by no means the case, because the relativity of the results will still hold good, and the comparisons of economics will remain reliable, in spite of any such changes. It is true that the unit prices for superstructure and those for substructure do not always vary in the same proportion; but eventually they settle down to an almost constant relationship. Even a permanent dislocation of their relativity, however, would not cause any material incorrectness in the results of the application of the curves to their legitimate function.

Conclusion

Attention is called to the fact that no where in this paper has any reference been made concerning the superiority, or the contrary, of any particular patented flooring; the problem investigated is solely one of economics. A consistent effort has been made to avoid advocating "special interests," with the understanding that discussers, likewise, will confine their comments to the intended scope of the paper.

DISCUSSION

Jonathan Jones,[3] M. Am. Soc. C. E. (by letter).—It should only emphasize the high regard in which the writer holds this paper, to state that its value will ultimately lie more in the method of approach and analysis which it sets forth, than in its statistical data. To the writer, it seems impossible to generalize the problem so that the unit costs involved will lie in the same pattern to-morrow as to-day; even the basic assumption that unit costs of flooring will be somewhat in inverse ratio to their unit weights, may not always hold.

Furthermore, all the factors that have been carefully analyzed in the paper for the general, may not enter into the particular, case. The most interesting case in which, within the writer's knowledge, the designing engineer erred in selecting a light-weight and expensive floor, involved several narrow 210-ft truss spans on adequate old piers. The cost of the piers, therefore, was not a factor in the problem, and to that extent at least the application of Fig. 5 would have been in error. Had the designing engineer, however, applied the logic of the author's method to those factors which did exist in his problem, and to the unit costs which he could foresee at his location, he would inevitably have found that he would have saved several thousand dollars by adopting a "standard" or even a "super-standard" floor.

The relationship between 4 cts per lb for secondary joists and 7 cts or more for an added stringer, would similarly be debatable in a given case. From such considerations comes the writer's feeling that, although the method herein given is invaluable, the most exact data should be applied to each particular case, and the author's data should be considered as illustrative.

The important effect of a variation in the data may be demonstrated by reference to Table 3. Using the author's unit costs, the minimum simple span at which the "standard" and the "50-lb" floor will be of equal cost is shown in Table 3(*a*); and in Table 3(*b*) these spans are re-calculated on the hypothesis that the cost of the "50-lb" floor has been reduced from $1.30 to only $1.15 per sq ft.

There are two generalizations in the paper toward which the writer would suggest considerable caution; these are found under the heading, "Suspension Bridges." With respect to suspension bridges it is stated "the lighter the flooring the less will be the first cost of the structure." The first requirement in approaching the design of any suspension bridge is to place a maximum limit on its flexibility, or deformation under partial live load. The weight of the flooring, and the consequent weight of the cables, have an important influence on stiffness. Granted that the design has been established as just adequately stiff, using a "standard" floor, then, if it is decided to use a lighter flooring and less wire in the cables, it will follow that the structure exceeds the pre-determined limit of flexibility, and the stiffening trusses will have to be increased in section or depth, or both, to restore the rigidity that has been taken out. Some, at least, of the money saved on cables and other main structure, therefore, must be spent on the stiffening system; and this is rather a pity because a dollar spent in the main structure is better invested than a dollar spent for local stiffening. This type of structure, therefore, calls for a complete comparative analysis.

---

TABLE 3.—EFFECT OF A VARIATION IN DATA, IN THE CASE OF SIMPLE-TRUSS BRIDGES

Item No.	Description	20-FOOT ROADWAY		40-FOOT ROADWAY	
		Carbon steel	Silicon steel	Carbon steel	Silicon steel
	(*a*) SPANS OF EQUAL COST, USING THE AUTHOR'S DATA				
1	Standard 9-in., 110-lb slab	$19.60	$19.60	$39.60	$39.60
2	Special 50-lb floor	34.20	34.80	71.20	72.55
3	Difference	$14.60	$15.20	$31.60	$32.95
4	From Fig	5	6	1	2
5	Read the span length of equal cost, in feet	300	380	270	335
	(*b*) SPANS OF EQUAL COST, IF COST OF THE 50-POUND FLOOR IS REDUCED FROM $1.30 TO $1.15 PER SQUARE FOOT				
6	Difference is less than Item No. 3 by:	$3.00	$3.00	$6.75	$6.75
7	New difference (Item No. 3 less than Item No. 6)	$11.60	$12.20	$24.85	$26.20
8	Span length of equal cost, in feet	230	320	180	240

With respect to cantilevers, the writer does not see the objection, from the æsthetic viewpoint, in using the heavier flooring on part or on all of the anchor arms. The change from the slab floor of the approaches to the special floor of the bridge spans must be made somewhere, and there seems to be no reason not to make it where it will be most beneficial. The prevention or, at all events, the minimizing, of live load reversal on the main truss-to-anchorage pins is proving to be extremely desirable on old cantilevers, even if it calls for longer anchor arms than former practice favored; to augment the downward force at this point by the use of heavy flooring on the anchor arms seems much more important than the question of where the tourist leaves the concrete and enters upon the metallic deck.

This paper is a most important contribution to one of the livest topics, from a money standpoint, now before the structural engineer, and thanks are due to Mr. Waddell for the effort expended upon it.

HENRY C. TAMMEN,[4] M. AM. SOC. C. E. (by letter).—In view of the many new developments in light-weight highway-bridge floorings during recent years and the interest of engineers in such floorings as evidenced by their increasing use, this paper is very timely. It should be of material help in the analysis of the economics of such floorings.

---

[4] Cons. Engr. (Ash-Howard-Needles & Tammen), New York, N. Y.

The author develops the relative economy of two floorings by the comparison of sums composed of two items: (1) The construction cost of the flooring and of certain special floor parts affected by the flooring design; and (2) the construction cost of the remainder of the superstructure and of the substructure.

For any flooring the amount of the first item (the cost of the flooring and certain special parts, shown in Table 2) is to be determined by each engineer for himself. It is to be expected that, for the same flooring and for the same structure, different engineers will reach somewhat different results. This might follow from variations in the design procedure (which is not yet standardized for many of the floorings); from variations in fastenings of the flooring to its supports (regarding which there are wide differences of opinion); from variations in minimum metal thicknesses; or from other causes. Some engineers will find it difficult to accept thicknesses of $\frac{1}{4}$ to $\frac{3}{16}$ in., or even less, as proper for a primary element carrying heavy loads such as a flooring, after having thought and worked for years with such members in terms of $\frac{5}{16}$ in. and $\frac{3}{8}$ in., or even greater thicknesses. The question will arise as to whether such thicknesses should be considered satisfactory at all, and also, whether a noncorrosive coating should be applied to the metal or whether the safe life of the flooring making use of such thicknesses should not be considered very much less than that of, say, the standard flooring.

To give a true economic comparison between several floorings, the writer would consider it proper to add to the flooring costs suitable amounts to cover an allowance for amortization of the flooring cost in cases where the safe life cannot be taken the same for the several floorings being compared. Similar allowances should properly be made also for differences in anticipated maintenance costs, including painting, snow removal (where applicable), and other maintenance items. For open-grate floorings the average annual maintenance painting cost may be in excess of 1 ct per sq ft, requiring the annual interest on an investment of 20 or 25 ct per sq ft, or more. For light-weight floorings having only a flat-bottom steel surface to be painted the cost will be only a fraction of the foregoing values, whereas for concrete floorings this cost disappears. Clearly the capitalized maintenance costs may vary substantially with the flooring type and may require consideration in any determination of comparative economy of several floorings.

With reference to the costs making up the second item (shown in Figs. 1 to 8) there should be no question regarding the portion of this cost which represents the superstructure. The superstructure cost is quite definite for each span length and, without doubt, the author's determination of it is as accurate as can reasonably be made. However, there may be material variations for different structures in the portion of this cost which represents the substructure.

Inspection of the cost curves for simple spans shows that minimum costs are found for spans between 200 ft and 300 ft for the various types of floor, for various roadway widths. Clearly, these are the economic span lengths for the grade line and foundation conditions which have been assumed by the author. Granting that, in actual structures, the span lengths in general conform closely to the economic, it would follow that for such economic structures the substructure costs and the saving effected by the use of lighter floorings which would result from the use of the cost curves, are too high for spans less than the foregoing and too small for greater spans. This applies also to the cost curves for cantilever spans where the several curves show minimum costs for spans between 700 ft and 800 ft.

In arriving at his substructure quantities, the author has used increasingly smaller piers with the lighter flooring. Many times the conditions are such that the pier shafts and, more frequently, the base sizes which would be adopted for standard concrete flooring are minimum sizes to give stability for the dead, live, wind, water, ice, and other load conditions for which provision must be made, and would not be decreased even if a light-weight flooring were used.

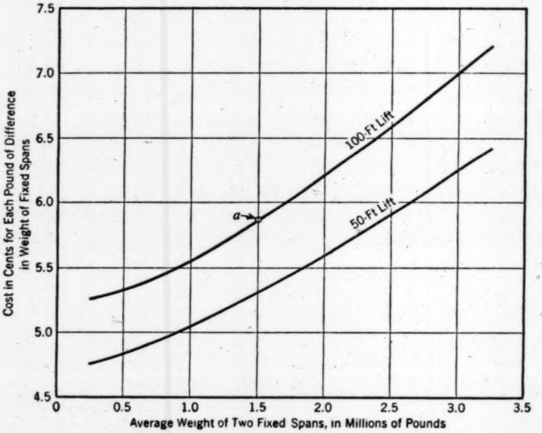

FIG. 11.—DIFFERENCES IN COST OF CONVERTING TWO FIXED SPANS OF DIFFERENT WEIGHTS INTO VERTICAL LIFT SPANS.

To make the cost data more generally useful in the analysis for structures with foundation conditions varying from those assumed in the paper, it would be helpful if the superstructure and substructure costs could be separated, and it is hoped that the author will find it possible to add this information in his closing discussion.

The writer has been particularly interested in the statements made with reference to economy of light-weight floors on movable spans. He has had occasion to make use of light-weight floors many times on such structures. The earlier applications on vertical lift spans involved merely the use of a light-weight aggregate in the concrete floor-slabs, these slabs being supported on closely spaced cross-beams to reduce slab thicknesses to a minimum. Even with the limited weight reduction practicable by this means, it was found possible with economy to ship such light-weight aggregate from its point of production in Kansas City, Mo., as far as San Francisco, Calif., and Canada, and in the latter case also to pay a duty on the aggregate.

Some years ago, the writer prepared estimates of quantities and costs for a group of vertical lift spans; from these he determined the cost of converting an ordinary fixed span into a vertical lift span and, finally, the increase or decrease in this conversion cost resulting from an increase or decrease of 1 lb in the weight of the fixed span. The results, revised to conform to present design practice, are shown in Fig. 11 in convenient form for use. They are based on towers with inclined rear legs supported on truss approach spans and on the conventional method of operation, with the machinery at the middle of the lift span, but should apply very generally also to spans with "tower drives". The make-up of the total cost, in cents, for Point *a*, Fig. 11, is as follows:

Tower and span metal	0.327 lb @ 5.5 ct × 0.75 =	1.35
Counter-weights	1.153 lb @ 1.0 ct × 0.75 =	0.87
Tower sheaves, shafts, and bearings	0.111 lb @ 15.0 ct × 0.75 =	1.25
Ropes	0.044 lb @ 20.0 ct × 0.75 =	0.66
Balance chains	0.052 lb @ 8.0 ct × 0.75 =	0.31
Operating machinery	0.028 lb @ 20.0 ct × 0.75 =	0.42
Motors, engine, house, etc.		1.00
Total		5.86

The same unit prices were used for all other points. The factor, 0.75, used with the assumed unit prices conforms to Equations (2), (3), and (4), given by the author which means that any reduction or increase in cost resulting from a change in quantity of an item is calculated by assuming that the quantity change takes a unit price equal to three-fourths that for the original quantity. In making a comparison of lift-span costs for two floorings, enter the curves with the average weight of the fixed spans for the two floorings. The difference in weight of the two fixed spans multiplied by the unit cost taken from the curves, will then represent the total cost saving in the movable span superstructure by use of the lighter of the two floorings under consideration.

Referring to Fig. 11, the average weight of two fixed spans may be expressed as $\frac{A + B}{2}$, in which A is the weight of the heavier fixed span; and B is the weight of the lighter of the two. Similarly, the total difference in cost may be expressed as $(A - B)\ C_x$, in which C_x is the cost per pound, taken from the curves of Fig. 11. The costs given by these curves include only the superstructure, and the savings shown by them for light-weight floorings are in addition to any savings for fixed spans that may be shown in the analysis presented by the author.

Fig. 11 indicates clearly the value of light weight in the flooring of a vertical lift span. The economy in a bascule span by use of light-weight flooring, in general, will be somewhat less than on vertical lift spans, due to the absence of ropes and to the fact that the dead weight of the span and counterweights has only a minor effect on the operating machinery and power requirements. The latter are determined largely by the wind loads. The saving in counterweight cost on bascules by the use of light flooring, on the contrary, may be several times that for lift spans, due to an increased ratio of counterweight weight to span weight and, frequently, also to a reduction in the unit weight of counterweights. The conditions for bascule spans are so variable that it is not practicable to show, by curves, the effects of weight changes in the span.

Miller McClintock,[5] Esq. (by letter).—Shortly after the first installment of an open steel-mesh flooring was made in the University Bridge, in Seattle, Wash., the writer, attracted by the possibilities of such light-weight construction for the decking of elevated, limited-way, structures, visited Seattle and made observations of the characteristics of the installation. On the basis of these observations and other tests and considerations, he recommended the use of this type of open steel-mesh flooring for a system of elevated limited highways then being designed for the City of Chicago, Ill. The incorporation of this type of light-weight flooring made it possible to reduce the size of various structural units and resulted in substantially lowering the estimated unit costs. The cost element, however, although important, was not the main factor which justified the recommendation. The writer was seeking a flooring completely flat in character and without pitch or crown for the purpose of improving the riding characteristics of the structure. To obtain such a flooring, it was necessary to design a decking which would be self-draining. This function of the open steel-mesh decking was very satisfactory and, in turn, eliminated certain structural costs in the design of drainage and run-off systems. The added economy of self-snow-cleansing was not without importance in the consideration.

A further very important economy was found in the capacity of this open steel-mesh flooring to pass a substantial percentage of normal light and air. In view of the fact that many of the elevated limited way structures, as designed, were contemplated for construction over existing streets, this was an element of very considerable significance. It eliminated in all or in part the necessity for day-time illumination for street surfaces under elevated structures and materially reduced contemplated damages to abutting property owners.

In the writer's opinion, this paper indicates a trend in thinking which should have substantial influence upon future designs of bridges and similar types of structures. There appears to be a particular need to obtain a simpler and less expensive type of construction for the thousands of grade-crossing separations which will be required in the near future.

---

[5] Director, Bureau for Street Traffic Research, Harvard Univ., Cambridge, Mass.

JOSEPH G. SHRYOCK,[6] M. AM. SOC. C. E. (by letter).—This timely and useful paper brings out many points of interest to the bridge and structural engineer, and emphasizes the fact that the lighter the floor, the greater will be the difference of cost per square foot over that of the conventional standard designs, and that there is doubtless a point on long-span bridges where the saving in weight of the floor-slab is offset by a sacrifice of lateral stiffness and rigidity of the structure.

All forms of solid floor construction, whether of concrete or steel, or a combination of both, form a horizontal girder capable of taking and absorbing a large percentage of the lateral stresses; this attribute is lacking in the open type floor.

All standard bridge specifications call for a specified $\frac{3}{8}$-in. minimum thickness of material, even for lacing-bars and redundant members, and only permit less thickness for lining and filling vacant spaces.

In 1900, the author presented[7] specifications for steel highway bridges which read as follows: "No metal less than $\frac{5}{16}$ of an inch in thickness shall be used, except for filling plates; and in important bridges this limit shall be increased to $\frac{3}{8}$ of an inch." Even with modern bridge steel, corrosion is still an important problem, and leaves only a relatively small factor for permanent strength on any $\frac{3}{16}$-in. member.

It would be advisable, therefore, to design an open-grate floor to meet standard specification requirements, as to minimum thickness of material and minimum size of structural rivets. To add a supplementary jack system to support the conventional open-grate floor properly, doubles the number of pieces in the floor system and their maintenance as well. Owing to the importance of future maintenance on all major structures, the modern engineering tendency is to use as few members as possible of rolled sections without lacing, thereby not only reducing secondary stresses to a minimum, but the cleaning and painting of the structure as well.

Whether it is of masonry or steel, solid or open, the floor-slab is a structural member of major importance; it receives not only the maximum concentrated wheel loads, but a greater percentage of impact than any other member in the bridge, and, in addition, is subject to abrasion or wear from moving loads.

On long-span bridges, each pound per square foot saved in the dead load of the floor becomes an important factor. Savings, therefore, of as much as 50% of the weight of the standard type of floor would effect economies without undue sacrifice of stiffness and rigidity. To reduce the weight of the floor to only 25% of the standard, however, could scarcely be secured without a sacrifice of these important requirements.

C. CALOR MOTA,[8] ESQ. (by letter).—In a course of bridge design for civil engineering students this paper is indeed a very useful one, and it is especially adapted to the practical use of the bridge designer. The most striking characteristic of the paper is its accurateness and completeness. All possible factors that may cause a change of metal weights in the trusses and floors per linear foot of bridge, are considered carefully and also any variations from the basic assumptions adopted. There is no question but that, in order to obtain the partial unit-cost curves of the paper, an enormous mass of data was necessary which only a designer of long experience could make possible. Table 2 is indeed a valuable tool for computing the total cost of structure per linear foot.

[6] Vice-Pres., Director, and Chf. Engr., Belmont Iron Works, Philadelphia, Pa.

[7] "De Pontibus", 1900, p. 226.

[8] Head, Dept. of Civ. Eng., Univ. of Puerto Rico, Mayaguez, Puerto Rico.

This paper, similar to that entitled, "Weights of Metal in Steel Trusses"[9], by the same author, constitutes a creditable contribution to technical literature in the economics of bridge engineering.

W. G. Fowler,[10] Assoc. M. Am. Soc. C. E. (by letter).—The problem of designing highway bridge floors has been attracting increasing attention from engineers during recent years, and the importance of this phase of bridge construction is attested by the number and variety of floors introduced during the last decade. To the best of the writer's information, this paper represents the first public attempt to correlate the knowledge relating to the various types of floors and to present it in a rational manner.

The curves and data presented by the author should prove invaluable as a means of making rapid comparisons between various types of floors in a preliminary study. The writer has made some studies of typical bridges with "standard flooring" and the pier heights assumed in the paper, and he finds a close check with the values presented by the author. However, if slightly different assumptions are made for the pier heights, results are obtained which depart rather widely from the costs indicated by the curves of partial unit costs. Because of this fact, the writer feels that these curves could be made much more valuable and easier to understand if the items of superstructure costs were separated from substructure costs. Substructures are usually a special problem for every bridge location, and the writer has never yet been able to set up curves or tables sufficiently comprehensive to be very useful in such studies.

The question of superstructure costs lends itself much more readily to standardization. Many engineers prepare their preliminary studies of a particular bridge structure by making parallel estimates of the superstructure from curves or tables, and of the substructure from special studies adapted to the location; and then they assemble the results in various combinations to determine the most economical arrangement. For this reason, the aforementioned division of data would be very useful.

Philip A. Franklin,[11] M. Am. Soc. C. E. (by letter).—It is with economics of first cost that the author has concerned himself and to that phase of the problem he has confined his paper. Very definitely, he states in his "Introduction" that he is "ignoring all claims for superiority * * *," and, in his closing paragraph, warns the discussers of the paper against advocating "special interests." All this is right and proper and the author has done a thorough and complete job of giving the profession a valuable working tool.

[11] With Bridge Decking Div., Blaw Knox Co., Blawnox, Pa.

The problem of choice of floor still remains and the duty of the engineer is to solve it by balancing the first cost of the various types against their desirability. This involves a knowledge of relative costs as determined by the curves and tables of the paper and also an appreciation of the values of the intangibles not susceptible of reduction to such curves and tables.

Mr. Waddell has simplified the problem by separating the factors into tangibles and intangibles and reducing the tangibles to as efficient a tool for solving first cost as the members of the profession have had presented to them for many years. If the economics of first cost were the ultimate answer to the problem of designing bridges, the consideration of such a paper would be a matter for a convention of purchasing agents and would not be worthy of the efforts of a body of engineers.

The curves and tables are only part of the necessary tools, however, and they must be used in combination with other tools in order to shape the materials entering into the design problem into a product commensurate with the reputation of the engineer. The consideration of this larger problem of the "Ultimate Economics of Highway Bridge Floors" is quite worthy of the efforts of the profession. It should not be hampered by the limitations of mathematics in the discussion, but the merits and shortcomings of all the various types of floors in common use should be reviewed; the factors which lead to desirable features as well as those which produce undesirable results should be listed; and conclusions should be drawn concerning the attributes of the perfect floor.

That there are defects in all the types of floors under discussion is well known to all bridge engineers. The heavier concrete floors are liable to surface abrasion, becoming rough and requiring re-surfacing. It is difficult to keep them from developing cracks due to negative bending, thereby allowing percolation of water to the supporting steel, and causing corrosion in places difficult to inspect and repair. The lighter concrete floors, containing aggregate of lesser weight, relieve the load on the supporting structure, but are still less abrasion-resistant than the heavier types. The filled-grid types are less subject to abrasion, and are still lighter; but they have a continuous metal surface beneath them that presents a maintenance and inspection problem in an inaccessible location. If they are not properly designed they are also likely to crack because of negative bending, with higher repair costs than the plain concrete floors. The inverted trough type of filled floor, if filled with alternate strips of thin and thick filler covered with a bituminous wearing surface, will become wavy under traffic and will require frequent re-surfacing. If this type is filled with concrete, the concrete and the surfacing will crack along the lines where the depth of the filler changes. It also has the same faults as the other all-metal under-surface floors in that it is more or less inaccessible for inspection and maintenance. The all-metal solid floor, with checkered-plate wearing surface, is also subject to corrosion on the under side and is anything but a safe driving surface in wet or icy weather, or even in summer when the grease-drip oils the surface. The markings soon wear off and only a plain steel plate is left.

All the solid surface types can only have good driving surfaces in fair weather. In snowy, sleety, or even in wet weather, they present a surface to traffic different than in dry weather and much more hazardous.

The open-grid floors require a secondary system of supports and complicate the original detailing and shop work as measured by present-day routine methods. Their greatest drawback is their novelty. For instance, the fact that some engineers "view with alarm" the supposed lack of lateral rigidity in the open floor when no consideration has ever been allowed on that score for any of the solid floors, is quite puzzling. Lateral bracing always has been, and probably always will be, designed for the full effect of some extremely high wind, and the effect of any stiffening due to the floor has been taken as an "added safety factor." The steel in the open-grid floors forms a rather effective horizontal girder of very large moment of inertia, with ample riveting to carry horizontal shear between the various longitudinal members. These, in turn, are welded to their stiffeners in the form of the transverse carrying members and these again to the longitudinal stringers forming a three-member laminated system much more resistant to distortion or to disruption than any concrete floor. To the writer, at least, the idea of putting metal in the lateral system, and in the stiffening truss of a suspension bridge, answers the requirement of "a dollar spent in the main structure is better invested than a dollar spent in local stiffening." It is better than to spend it for more costly floor construction which, formerly, was never credited with lateral stiffness.

Another principal fallacy is that water, in itself, is responsible for corrosion. Corrosion is due to water in combination with other compounds and conditions, and the longer these factors are allowed to remain in combination the faster the corrosion proceeds. Conversely, the speedy breaking up of the combination is the best preventive of corrosion. The sunlight goes through an open grid to the supporting stringers and floorbeams. Each passing vehicle fans the grid and the supports with an intense blast of air. The drip from the engines coats the surface of the grid members. The dirt and dust falling through the grid are dried by the ventilation and forced draft and are blown away so that corrosion does not attack either the supports or the much-feared $\frac{3}{16}$-in. metal of the grid.

Naturally, the consultant is interested primarily in his reputation for conservative design; the fabricator's engineer is interested in securing a contract by offering a cheaper structure than his competitor while remaining within the letter of the specification. The inventor, whether or not he is in either of the foregoing classes, is interested in having his "brain-child" accepted in "the best circles" and in securing a royalty for it.

This leaves the prospective owner or the unbiased engineer in the position of having to satisfy himself as to the desirability of the various floors offered, and then to choose from them by balancing the costs against the merits. Since only approximately 10% of the membership of the Society is directly interested in bridges and probably not 10% of these are in either of the aforementioned biased classes, it should be apparent that the only hope for any of the other 90% of the members to "sift the wheat from the chaff" is to make their own investigation into the intangibles not covered in the paper.

J. A. L. WADDELL,[12] HON. M. AM. SOC. C. E. (by letter).—The discussion of this paper, although not as extensive as the writer had hoped, has served to emphasize several important features. The points raised by Messrs. Jones, Tammen, and Franklin are of especial interest.

Messrs. Tammen and Fowler have asked for a separation of the substructure and superstructure costs used in preparing the curves of Figs. 1 to 8. On the average, the substructure for the open-grate flooring was found to cost about $14 per lin ft of bridge less than that for the "standard" flooring for a roadway width of 45 ft, and about $7 less for a 20-ft roadway. Cost differences for intermediate types can be interpolated with sufficient accuracy. For the case mentioned in the second paragraph of Mr. Jones' discussion, the substructure differential should be subtracted from the difference found from the curves of Fig. 1 or Fig. 5.

Mr. Jones emphasizes the value of "the method of approach and analysis" which the paper sets forth, but questions whether the findings are sufficiently general for the curves to be used in actual comparisons of cost. He states: "From such considerations comes the writer's feeling that, although the method herein given is invaluable, the most exact data should be applied to each particular case, and the author's data should be considered as illustrative."

In making his criticism, Mr. Jones has apparently overlooked the fact that Figs. 1 to 8 give merely the combined costs of substructure and superstructure to carry floorings of various weights, and that the costs of the floorings themselves are to be determined and added separately. Tables 1 and 2 give data regarding the costs of various floorings that are fairly representative of present-day light-weight floors; but it is assumed that an engineer, in dealing with a specific problem, will determine the weights and costs of the actual floorings he is comparing, and will use his results rather than those of Tables 1 and 2. Ample provision is made, therefore, for variation in flooring costs and for the future development of new types.

Table 3 of Mr. Jones' discussion, showing the effect of a variation in floor costs, is correct; but this is no argument against the accuracy of the results found from Figs. 1 to 8, for the reasons just stated.

Messrs. Jones, Tammen, and Fowler have referred to factors affecting the accuracy of the diagrams themselves, such as variations in prices and in the substructure. They have, however, over-estimated the relative importance of such variations. Suppose, for instance, a silicon-steel highway bridge of 400-ft simple spans, carrying a 45-ft roadway, is being considered, and that comparison is to be made for the "standard" flooring, a 60-lb flooring, and an open-grate floor. From Fig. 2 and Table 2, the values in Table 4 are obtained, the separate items for substructure and superstructure being taken from the computations on which the diagrams were based.

---

[12] Cons. Engr., New York, N. Y. Mr. Waddell died March 3, 1938.

TABLE 4.—COMPARISON OF COSTS

Item No.	Description	Type of Flooring		
		Standard	Sixty pound	Open grate
	(1)	(2)	(3)	(4)
1	Superstructure	$311.40	$282.30	$263.00
2	Substructure	111.00	103.50	97.30
3	Cost, without deck	$422.40	$385.80	$360.30
4	Cost of deck	39.60	67.80	88.60
5	Total	$462.00	$453.60	$448.90
6	Excess cost over open-grate type	+$13.10	+$4.70	0

If a 10% change in superstructure unit prices is assumed, the differential between the "standard" and open-grate floors would be changed by $4.84, and that between the 60-lb and open-grate floors by $1.93. A considerable change in the substructure conditions would mean merely a change in the differential between the "standard" floor and the open-grate flooring ($13.10), or in the differential between the 60-lb floor and the open-grate floor ($6.20). In most instances, such changes in costs would not be great enough to upset the relative economics of the floors being considered; and where the relative standings were affected, it would merely be because the costs for the types being compared were so nearly alike that it would make little difference, as far as cost is concerned, which type was used. In the case under consideration, a difference of $5 per ft would mean only a 1% variation, and even $10 per ft would amount to only 2 per cent. Such differences are well within the ordinary errors of estimating. Furthermore, changes in the general price level can be allowed for by multiplying the results taken from the diagrams by a correction factor, and a major difference in substructure conditions can be allowed for by increasing or reducing the substructure differentials given in the second paragraph of this closure.

Since this paper was published the writer has had occasion to prepare several estimates affording an opportunity for a check on the curves in Figs. 1 to 8, and has found them absolutely reliable.[13] A further study, made in connection with the preparation of this closure, shows that a considerable variation in pier heights makes no appreciable difference in the relative costs of different types of floors.

Mr. Jones is correct in calling attention to the fact that lightening the floor of a suspension bridge will require an increase in the weight of the stiffening trusses. In most cases, however, this means simply a reduction in the saving to be realized by the use of a lighter floor. For a comparatively short span, where the saving in other parts of the bridge is not large, the increase in the stiffening trusses will be small; and, for a long span, on the other hand, where the increase in stiffening truss weight will be considerable, the saving in other parts—floor-system, suspenders, cables, towers, and anchorages—will also be large.

---

[13] "Quick Estimating of Economic-Bridge Costs," by J. A. L. Waddell, Hon. M. Am. Soc. C. E., and Shortridge Hardesty, M. Am. Soc. C. E., N. Y., John Wiley & Sons.

Referring to cantilever spans, there would be no objection to using a heavy floor on the anchor spans of a three-span Type *A* cantilever, and a light floor on the central span. For a Type *C* cantilever or a long bridge consisting of an alternation of anchor and cantilever spans, it would be unsatisfactory, from the standpoint of both appearance and traffic, to use one type on the anchor spans and another on the cantilever spans.

Mr. Tammen mentions the fact that different engineers will reach different results for the same flooring, due to variations in design procedure, details, minimum thickness of metal, and allowances for maintenance and amortization. Such considerations do not affect the usefulness of the paper in any way, because it is assumed that each engineer will determine for himself the total costs and allowable span lengths of the floorings he is comparing. Allowances for maintenance and amortization are difficult to determine, since relative costs and life for light-weight floors and older types of heavy floors are not yet known.

Mr. Tammen criticizes the use of thinner metal in the flooring rather than in other parts of the superstructure—and possibly his comment is truly sound; but it must not be forgotten that, if the light-weight flooring should either rust out or wear out, it could easily be repaired or replaced, whereas thin metal in the superstructure proper could not. It is either the manufacturers or the patentees of such floors who have determined the thickness of their products; and if these sections are computed properly for strength, experience will ultimately tell whether the use of the thin sections is truly economical.

Mr. Tammen's data relative to the savings resulting from the use of light-weight floors on movable spans are interesting and valuable, and the writer endorses them heartily.

It is difficult to agree with Mr. Shryock's conclusion that floor weights can be reduced to 50% of the weight of the standard type "without undue sacrifice of stiffness and rigidity," but that a reduction to 25% "could scarcely be secured without a sacrifice of these important requirements," because both the percentages quoted are purely arbitrary. The 540-ft spans of the Marine Parkway Bridge over Rockaway Inlet in New York City, which are paved with open-grating, are perfectly stiff and rigid under traffic. It should also be noted, as stated by Mr. Franklin, that an open-grate floor, when properly detailed and thoroughly connected to the supporting steelwork, forms an effective horizontal girder.

To Mr. McClintock and Professor C. Calor Mota, the writer desires to express his deep appreciation of their hearty endorsements of his technical efforts. Mr. Fowler should not forget that the sole object of the paper is to compare the economics of different types of flooring and not to provide the data for making cost estimates of bridges.

Mr. Franklin's discussion is most important. The writer endorses unequivocally all the points he raises, and specially commends the division of the conditions into "tangibles and intangibles"; moreover he concedes that the latter are, and should be universally considered by far the more important. In selecting the type of flooring for a highway bridge, the prime requisite certainly is safety; and economy in first cost should always be a subordinate consideration. Safety from accidents through skidding should always be a primary consideration, because human life and human welfare are endangered by such accidents.

Mr. Franklin has prepared his discussion very skilfully, in that he has handled the subject of "intangibles" without any reference to patented floorings or special interests. Nevertheless, he states:

> "* * * The consideration of this larger problem of the 'Ultimate Economics of Highway-Bridge Floors' is quite worthy of the efforts of the profession. It should not be hampered by the limitations of mathematics in the discussion, but the merits and shortcomings of all the various types of floors in common use should be reviewed; the factors which lead to desirable features, as well as those which produce undesirable results, should be listed; and conclusions should be drawn concerning the attributes of the perfect floor."

Such a general open discussion would be of truly great value.

The objection to open-grid floors that they "require a secondary system of supports and complicate the original detailing and shopwork" is an economic one, and, therefore, pertains to the "tangible" group of factors; consequently, it is taken care of by the cost-curves and tables of the paper. From the standpoint of safety, the principal advantage of the open floor is its elimination of lateral skidding, even during times of snow and sleet.

The Marine Parkway Bridge, previously mentioned, will provide an excellent measure of the safety, the durability, and the cost of maintenance for open flooring, as compared with the "standard" solid flooring; because, on the three long main spans, open-grate flooring is used, whereas all the approach spans have concrete flooring. Experience during one winter may settle the question of the comparative safety of the two types, but years will be required in order to determine the comparative maintenance costs.

In the writer's opinion, the open flooring has come to stay, and is destined to be one of the standard highway-bridge floors of the future.

In closing this paper, the writer desires again to thank all the engineers who have so kindly discussed it, especially Mr. Jones and Mr. Tammen, whose skepticism concerning accuracy of results has enabled him to show that such skepticism is unfounded, and Mr. Franklin who indicated the existence of "intangible" as well as economic factors in the comparison of bridge floorings.

FEDERAL RESPONSIBILITY FOR FLOOD CONTROL

By the Hon. James J. Davis[1]

Since Colonial times, floods have taken their toll annually in various sections of the country. Experience in Pennsylvania is typical, and a few comments on conditions in that State will suffice to indicate the importance of the problem, not only there, but throughout the United States.

Flood Problems in Pennsylvania

Prior to 1937, about thirty major floods had been recorded on the Delaware River, thirty-five on the Susquehanna, and about fifty on the Ohio. (These three streams together drain approximately 95% of the State.) Numerous floods localized on their smaller tributaries have also occurred frequently and have caused serious damage.

The flood of June 1, 1889, is the greatest on record in the Susquehanna Basin. Although the storm was concentrated over the water-sheds of the Juniata and the West Branch of the Susquehanna River, most of the central and eastern part of the State suffered unparalleled losses; at Johnstown, in Cambria County, 2 142 lives were lost, and a large part of the city was destroyed.

The Pittsburgh Flood Commission estimated the flood toll to the City of Pittsburgh alone, from 1898 to 1908, at $12 000 000, of which $6 500 000 was caused by three floods in 1907 and 1908. The total financial loss along the Allegheny River resulting from the 1913 flood amounted to $720 000. Damage in the Shenango and Beaver Valleys from the same flood was $2 100 000. In August, 1915, in the City of Erie, thirty-four people were drowned and damage amounting to $2 000 000 resulted from a flood in Mill Creek. In July, 1931, Norristown suffered a loss of $1 000 000 as the result of floods in two small creeks traversing the Borough. York lost $260 000 in 1884 and $4 360 000 in 1933 from floods in Codorous Creek.

Even these figures, of course, become insignificant in comparison with those for the general floods of 1936, in which Pennsylvania was one of the heaviest sufferers. The flood damages throughout the East during that year are variously estimated at from $250 000 000 to $500 000 000.

Floods can be controlled by storage or retarding basins, diversion channels, stream channel improvements, and levees or embankments. Protection generally may best be secured, not by any one of these methods, but by a combination of several of them. For example, storage basins, together with certain channel improvements, have been recommended for flood protection for the City of Pittsburgh. A combination of channel improvement and levee or dike construction has been suggested along the North Branch of the Susquehanna River to protect the Wyoming Valley. A combination of retarding basins, diversions, and channel improvements has been in successful operation for years at Harrisburg, Pa.

---

[1] U. S. Senator from Pennsylvania, Pittsburgh, Pa.

In the Shenango and Beaver Valleys, in Western Pennsylvania, flood control by storage basin retardation alone has been effected by the completion of the State Pymatuning Reservoir Project, although the primary purpose of this reservoir is to provide sufficient water during the dry season for domestic and industrial use.

A carefully determined public policy for control and supervision of the streams of the Commonwealth was adopted and put into effect in 1933, with the enactment of the Dam and Encroachment Act, which made it unlawful for any one to construct any "water obstruction" without a State permit. Since that time, stream channels of a section adequate to discharge the maximum expected floods have been conserved and protected. Channels that had been encroached upon and restricted so that they were unable to pass floods without overflowing, have not been allowed to become worse, and, in various places, serious obstructions to the flow have been modified or removed and the channels have been improved. In communities subject to flood damage the State has made a number of surveys and hydraulic studies. Channel lines, marking the permissible limits of new construction, have been established in Johnstown, York, Manayunk, Sharon, New Castle, Butler, Reading, Norristown, Scranton, and Erie, and existing encroachments on these lines are gradually being removed.

The major flood-control problem in Pennsylvania—protection for Pittsburgh and the Upper Ohio River—was studied under the direction of the Pittsburgh Flood Commission from 1908 to 1912. In the latter year, the Commission recommended the construction of seventeen retarding or flood-storage reservoirs distributed over the drainage areas of the Allegheny and Monongahela Rivers, supplemented by a river wall at Pittsburgh. The cost was estimated to be about one-half the direct loss that would otherwise be caused by flood damage to the city within a 20-yr period. Between 1924 and 1929, United States Army Engineers studied the problem and developed many additional valuable data.

State legislation approved in 1931 authorized the Water and Power Resources Board to take up the study and develop a plan of flood control, and empowered it to proceed on its own authority, or at the request of some outside person or agency, to improve stream channels, build levees and diversion channels, and to construct retarding storage basins for flood control. The Board and its agencies were further empowered to "enter upon, take, appropriate or injure any land or lands", and damages sustained thereby are to be paid by the Department of Forests and Waters. In 1933, the Commission submitted a new plan, based upon all the essential data developed to date, providing for the construction of ten storage reservoirs, seven in the Allegheny water-shed and three in the Monongahela water-shed, at an estimated cost of $57 500 000.

It is natural to ask why a project so meritorious as this one has remained so many years in the planning stage. The answer is plain. The Allegheny River has portions of its water-shed in two States—New York and Pennsylvania. The Monongahela River has its water-shed in three States—Maryland, West Virginia, and Pennsylvania. The proposed reservoirs would be in several States and would affect the flow of the stream in each. It is not possible, therefore, for any city or county, or even for the State of Pennsylvania, to undertake to complete the project in its entirety, or in the comprehensive manner necessary, without assuming more responsibility than it rightly should. National control and action are necessary. Prior to 1936, however, the interest of the Federal Government in large streams was confined, except in a few cases, to the problems of navigation. The main question of concern to the National Government was how much the destruction of a forest, or the building of a bridge or a reservoir, would affect navigation.

More recently, however, a new consciousness has been developing. It is now recognized that flood control is a problem of major national significance, and that it deserves consideration in its own name and on its own merit. It is recognized that what is done to control floods in one part of the country vitally affects the lives, the property, and the well-being of people in other parts.

Federal Participation in Flood Control

The first aid from the Federal Government relating to flood control pertained to the Mississippi River and was provided in the Swamp Land Acts of 1849 and 1850. By these Acts Congress granted to the several States the swamp and overflowed lands within their borders and provided that the proceeds from the sale of the lands must be spent for drainage and flood protection. Congress passed another Act in 1850 that must be given an important place in any consideration of the problems of the Lower Mississippi Valley. This act "directed a topographical and hydrographical survey of the delta of the Mississippi River, with such investigation as might lead to determine the most practical plan for securing it from inundation." The report of Charles Ellet, a Civil Engineer working for the U. S. Army Engineers, was the result of this first official study of flood control by the Federal Government. The Ellet report came in 1852 and concluded that the control of the floods on the Mississippi was the nation's duty and that it was a question that "must be decided by the justice and humanity of the nation." That statement showed a definite trend in official thinking.

The Civil War halted the movement for flood control. In 1878, however, the Rivers and Harbors Bill provided $1 000 000 for aiding navigation on the Mississippi. The money was spent by the Board on the Improvement of the Mississippi River under the supervision of the U. S. Army Engineers. This Board was composed of Army engineers who favored levees for improving navigation. Thus, the Army engineers came to support those who wanted levees to control floods. The combining of the groups desiring flood control and the groups interested in navigation was evident in the debate on the bill creating the Mississippi River Commission in 1879, which put the United States definitely into flood-control work, and which probably stands as the most important piece of flood-control legislation in the entire history of the country.

One of the strongest arguments generally advanced for flood control by the Federal Government is that the United States owns the rivers and has paramount jurisdiction over them. The conclusion that the United States should not permit its property to damage the citizens of any section is the natural outgrowth of ownership. The interstate nature of the flood-control problem has furnished another reason for Federal responsibility. The contrast in size between the gigantic drainage area of the Mississippi River as a whole and the small territory drained by the Lower Valley—the region that suffers most from floods—is striking. The Mississippi Basin contains 1 250 000 sq miles of territory, 41% of the area of the United States. It includes all or parts of thirty-one States, the combined population of which is one-half that of the entire nation. The river system includes 15 000 miles of navigable streams and many thousands of miles of non-navigable ones. The contention that the interstate nature of the problem makes it a national one grows much stronger when it is understood that the area that suffers most from floods contributes little or none of the water that causes them.

The suggestion has frequently been made that the cost of flood control should be borne by the various States in proportion to their responsibility for the floods, but the difficulties of apportioning costs on such a basis appear to be insurmountable The State of North Dakota and the State of Pennsylvania, for example, both contribute water to the Mississippi, but it would hardly be possible to say how much the flow from either State adds to the floods on that stream. The problem is sufficiently complex when only the natural causes of floods are considered; it becomes much more so when the acts of States and individuals in regard to drainage and flood control are taken into account. Works built for flood protection by citizens of one State may pile up the water and spread it over the lands of the citizens of another State. On the other hand, the vigilant have often been inundated because of the negligence of their neighbors. Hence, the demand for Federal control.

Most of the people believe that the Federal Government exists for the practical purposes of protecting the general welfare. In considering the general welfare as related to flood control the humanitarian and the economic phases can not be entirely separated. The great sacrifices, suffering, expenses, and property losses of those at the mercy of the floods are all intertwined.

A consideration of Federal responsibility for flood control calls for thought as to the causes of floods. Apparently, all agree that the causes have many far-flung ramifications. They extend even to the grazing of cattle and sheep far in the interior, when over-grazing of the lands causes rapid run-off and erosion. Even the direction of a furrow in plowing may affect the quantity of water that flows from the surface of a field and the amount of sediment it carries. Paved streets and sewerage and drainage systems have added at least to local flood problems by causing both a heavy and a rapid run-off. Many cities with splendid drainage systems do not realize that they have been hastening floods down upon their neighbors. Even the construction of hard-surfaced and well-drained highways throughout the country has added to the areas from which run-off is heavy and rapid. Many of these highways have been built under Federal specifications and with the aid of Federal funds. Highways, railroads, cities, and industrial and commercial enterprises have aided in piling up the flood-waters by encroaching upon the natural channels of streams with bridges, embankments, piers, terminals, and other structures. In the case of navigable streams such encroachments have been made with the express permission of the Federal Government, which thereby has become an agent in creating these encroachments, and, therefore, in causing destructive floods.

However, the influence on floods of such factors as those just mentioned must be relatively small in comparison with that of the general deforestation, drainage, and development of the vast valley territory. Large areas of swamps and lowlands have been drained, forests have been cleared away, and the land has been used in such a way as to cause much erosion and rapid run-off. The hills pour torrents of turbid waters through man-made gullies into the rivers, filling their beds with mud, and causing them to overflow their banks.

Arguments for Federal Responsibility

Many believe that flood control is the duty of the Federal Government for the reason that no other power exists that is able to cope with the problem. In 1879, the Hon. James A. Garfield stated in the House of Representatives that it was "too vast for any State to handle; too much for any authority less than that of the nation itself to manage." When it is realized that the Federal Government, the States, levee boards, cities, counties, railways, and individuals have been building levees, and that ten agencies in the Departments of War, Interior, Commerce, and Agriculture, to say nothing of the PWA and WPA, have had authority in the development and control of streams, it appears rather remarkable that the task has been performed as well as it has; but a satisfactory public policy can never be developed under these conditions. Each organization naturally outlines its own problems and proceeds to work them out with little reference to those of other groups. This situation has caused a widespread demand for a unified control.

Added to these reasons for Federal responsibility in flood control are important considerations of interstate commerce, including the postal service, public health, and national defense. They are so obvious as to require no elucidation.

Federal control has been delayed because the construction of protective works costs large sums of money, because opponents have claimed that it constituted a reclamation project for the benefit of private property, because sectionalism has invested proposed flood-control legislation with the objectionable "pork-barrel" feature, because there has been disagreement as to the best methods of handling the problem, and because some have held that it was unconstitutional. None of these arguments has weighed so mightily as the general inertia of the public in forcing the issue. Organized representation of the flood-control cause in Washington, D. C., has not been sufficiently persistent or powerful.

Several strong points for the constitutionality of flood control by the Federal Government have been advanced, but the bulwark of most of the arguments has been the jurisdiction of the Federal Government over interstate commerce. The early participation of the United States in flood control was based entirely on the proposition of improving navigation to facilitate commerce on the Mississippi. Congress and the public paid particular attention to the provisions in the early appropriation acts that no part of the money should be spent for levees to prevent injury to lands by overflow. This point of view has long prevailed. However, in 1917, proponents of flood control sought to establish the right to control the Mississippi under the commerce clause on a wider basis than that of merely improving navigation. They frankly stated that it was a flood-control measure. They took the position that legislation for the improvement of navigation had been "predicated upon the power of Congress to regulate commerce", that the word, "navigation", did not appear in the Constitution but had been written in as a part of the interpretation of the commerce clause. They turned their attention to statements of legal authorities and to Court decisions, apparently with satisfactory results.

The general welfare clause has naturally furnished a strong point for those who sought to prove the constitutionality of flood control by the United States. It has been suggested that the Constitution has been expanded by usage and by interpretation to include many things under this head. To many the Government had as much right to make land suitable for habitation by protecting it against floods as it did to give away the public domain. Congress has been very liberal in voting money to relieve suffering among the victims of floods; little question as to the constitutionality of such aid has ever been raised. It has been urged with apparent logic that appropriations for flood protection mean as much for the general welfare as appropriations for the relief of flood sufferers and that they are, therefore, just as constitutional. Chief Justice Story maintained that if the benefit was general, whether it was located in "one State or several", Congress could appropriate money for it because it was for the general welfare.

The problem of flood control must be regarded fundamentally as one of engineering, and the Engineering Profession deserves recognition for the support it has given to the Federal program. Engineers have appeared times without number as witnesses before Congressional committees. They have passed many resolutions in State and National conventions demanding Federal control. No other group of financially disinterested persons has more generally urged complete control of the floods of the Mississippi and its tributaries.

The people of the United States have finally realized that floods will continue to increase in importance. Floods have not become more frequent, but as the population grows, they are becoming increasingly more destructive. Property values and the density of population have already reached such a status that millions of persons now live in areas that are without adequate protection. Flood control is now a national problem and must be considered fully as a Federal responsibility.

PROBLEMS IN DEVELOPING A NATIONAL FLOOD-PROTECTION POLICY

By Abel Wolman[2], M. Am. Soc. C. E.

Synopsis

After every major catastrophe public demand for preventive action reaches its peak and the solutions proposed are as varied as the interests involved. In this respect the March, 1936, floods were no exception. Demands for immediate action, for Congressional appropriations, for financial programs, filled the lay and technical journals. History teaches that in such periods of stress, judgment and logic are unduly influenced by emotion. It is frequently the most unfavorable time in which to formulate policies for control. When public interest is at its height, on the other hand, is the most fruitful period in which to make real progress in the solution of a difficult national problem.

Most thoughtful students of flood-protection procedure would probably agree on the following facts:

(*a*) Engineering studies of past destructive floods are by and large incomplete.

(*b*) Detailed and carefully prepared programs for immediate flood protection are likewise lacking in many areas, although reconnaissance studies are available.

(*c*) In the development of principles and policies much more than engineering information and conclusions is needed.

(*d*) A kind of statesmanship and creative thinking, not yet fully developed, is required, which will balance local and national needs and costs against assessments of benefits.

(*e*) A new sense of social responsibility on the part of local areas is needed.

(*f*) Protection for a local area should be designed not only to meet the flood-control requirements of the area, but for the social and economic advantage of the nation in respect to all water uses.

A large number of reports by Federal or local agencies have been prepared from time to time. The most important undertakings of this type are those known as the "308 Reports" of the Corps of Engineers, U. S. Army. Because of the limitations under which these documents were prepared, they cannot all be considered as of completely definitive character. In such instances adjustment is needed, and, in general, a continuing review is desirable.

The interval between the preparation of reports, where they have been made, and the actual initiation of construction work, is likely to be long.

---

[2] Chairman, Water Resources Committee, National Resources Committee, Washington, D. C.; Prof. of San. Eng., Johns Hopkins Univ., Baltimore, Md.

Almost a quarter of a century elapsed, for example, between the preparation of a document on the Muskingum River floods and the building of the control structures.

An analysis of national shortcomings in flood-protection measures soon discloses that the problem is highly complex and that it cannot be reviewed upon so simple a basis as flood protection *per se.* Although many engineers and most laymen would urge strongly the correction or prevention of flood damages, even a superficial review of the situation makes it clear that few flood-protection programs should proceed without consideration of the relationship of these measures to other possible uses of water. When such reviews are undertaken, simplicity of approach gives way to complexity of use and to conflicts in purpose and in policy.

Because of these difficulties in orientation the writer considers it wise to present a brief analysis of the various aspects of determining upon a national flood-protection policy and to outline what measures are under way, as of 1937, to clarify some of the problems involved. In this attempt, it will be apparent that considerations other than engineering loom large in the final solution. Nevertheless, any generalized program for water use must rest obviously upon detailed and careful engineering analysis. In periods of stress and haste this axiom has not always been observed. It is a prerequisite to all that is written in this paper.

ENGINEERING ASPECTS

What are the links in the chain of engineering evidence that should be available before a national policy can emerge?

To engineers, of course, the first element of deficiency is in incomplete hydrologic data, not only for floods but for every form of river run-off. The Water Resources Committee of the National Resources Committee, in several of its sub-committee publications, has called attention to these deficiencies in basic hydrologic data. Whether these deficiencies are corrected in the future depends upon such organizations as the Society and upon lay support.

Without such book-keeping of hydrologic data, no policy can be adopted with complete confidence. The program should be nation-wide, continuous, and technically accurate, and the results should be regularly interpreted and reported to the profession. Discontinuous observation, although perhaps better than nothing, does not fully meet the requirements.

Even in 1937, detailed analyses of major floods leave something to be desired, although the "308" reports of the War Department and the publications by the Miami Conservancy District, the United States Geological Survey, and the Bureau of Agricultural Engineering, have added material of incalculable value in recent years. The studies should be extended. Findings are spotty geographically, and methods of analysis and of forecast still need improvement.

In determining the effects of different procedures on the control of floods, in some instances the profession is still divided, and the heat of discussion has so far prevented a calm analysis.

What part detention reservoirs, channel improvements, zoning control of encroachment, forestation, soil conservation, small dams, and so-called "upstream engineering" should play in a general water-resources program, still remains to be demonstrated conclusively. The hiatus between claim and substantiation in fact is wide, and competitive claims are scarcely sufficient basis for a permanent policy. Only detailed field and office analysis of water resources control can disclose the relative merits of the various devices and procedures. In this regard, "newspaper experts" have not been the only delinquents. Members of the Engineering Profession have permitted themselves to be diverted into defensive or offensive controversial fields where their capacities for objective analysis have suffered or disappeared. At times, little or no interest has been exhibited by those individuals who should be most interested, in the multiple-use problem in water-resources development. Not all the present difficulties of approach may be ascribed to misguided enthusiasts among the laymen. After all, engineering guidance for public opinion is more necessary to-day than at any other time in the past. Aloofness, professional provincialism, political partisanship, are all strange bedfellows for engineering judgment. Engineering texts, of course, are filled with principles of caution and logic in the matter of water-resources development; but how frequently are they ignored! For example, the zoning principle suggested by the late Allen Hazen, M. Am. Soc. C. E., many years ago, for application in flood areas, when discussed at all to-day is met with scoffing in some groups and with complete disregard in others. Yet as a flood-protection measure, it may some day have the place in the sun that it undoubtedly deserves.

FINANCIAL ASPECTS

The engineering aspects of water-resources control lend themselves to quantitative determination and decision. This is not the case, however, with the financial aspect of the problem. The simple statement that water-resources development, and flood protection as a unit thereof, should be financed largely by local interests, is sound and clear on paper. No one can take issue with this statement of policy; but its practical application requires discussion.

It is not invariably true that a water-resources program is restricted to the confines of a single State. Often two or more States are involved. Often reservoir sites in one State may be used for the control of flow in three or four down-stream States. In this setting, the concepts of damages, benefits, and allocation of the costs of correction are decidedly confusing.

Any one reviewing the damages presumably caused by destructive floods is at once impressed with the absence of any standard criteria for evaluation. Any two agencies, Federal or local, are likely to arrive at separate estimates of the flood damages in a given area that will differ widely. These deficiencies in approach led the Water Resources Committee to appoint a sub-committee in December, 1936, to study the criteria for the evaluation of flood damages. No one believes that an immediate standardized methodology in this field is desirable, but it should be possible to present certain major criteria of approach that would put such estimates on a more scientific basis. Likewise, no one believes that a methodology must be devised which is a substitute for long experience. An analysis of practical criteria may clarify, however, the concepts even for the experienced observer.

Most people assume that the economic justification for flood protection is simple to evaluate. It is surprising to find how little information is available, not only on specific flood damage, but on the general, special, and intangible benefits that might arise from the initiation of flood-protection measures. Various procedures have been used from place to place, but it is rare that the details of such principles of benefit evaluation are presented so as to be readily subject to check.

Since assessment of local benefit, presumably the base of local participation, is still in a nebulous state, the difficulty of adhering to what appears to be a sound policy becomes more complicated as each flood-protection project comes under review.

The pressing question of how much central responsibility for flood protection the Federal Government should assume, is more difficult to answer when viewed in the light of specific undertakings than when stated as a general principle. One reason for this difficulty is that the mere definition of "Federal" interest is continually undergoing adjustment. This is not solely due, as many believe, to the so-called rise in central bureaucracy. It may be the result and the penalty of increasing national integration. It may be the result and the penalty of growth of population and of the difficulty of separating local from regional hazards and corrective measures.

It is a Jeffersonian principle that government in the United States should result "in the partition of cares, descending in gradation from general to particular, that the mass of human affairs may be best managed for the good and prosperity of all." This precept is valid only until its application under the pressure of such difficulties as those encountered in water-resources development make deviations therefrom necessary. The question is how far such deviations are wise; how much may be accomplished within the framework of State autonomy; how well drainage-basin enterprises may be developed within that framework; and what re-adjustments in theoretical principles, if any, the pressing problems of water resources may make necessary.

In such a complicated problem it is obvious, at least to the writer, that slow motion is a sound principle of action. Heroic changes in procedures of Federal-local responsibility must be approached with caution. At the same time, it may be questioned whether such approaches should be so congealed by precedent no longer applicable, that no comprehensive treatment of water resources is possible.

In the allocation of financial responsibility, it should also be remembered that a simple formula may be a first necessity. The Flood Control Act of 1936 illustrates, however, that in the desire to adopt a simple formula for local participation, many inequities necessarily arise. The percentage to be paid by local areas in terms of land and rights of way may vary from 10 to the maximum legal limit of 50. The intent of such a Congressional Act may be wise, but its application is likely to be inequitable. A logical substitute for the simple formula type of Congressional approach lies in moving administrative control. This gives rise in turn to the charge of increased bureaucracy, although the nature of the water-resources problem would appear to pre-suppose the necessity of avoiding a rigid formula for evaluating local and central responsibility.

When the problem is extended to the evaluation of benefits and costs in multiple uses of a stream, the difficulty of using a formula on a national basis becomes even more apparent. In this field, there may be no escape from continuing administrative adjustment and evaluation. This will no doubt create a variety of geographic apportionments of costs, and necessarily much argument. Here, again, is a fruitful field for the best technical thought of the country.

The formulation of a national fiscal policy with reference to any important public undertaking has always been beset with the necessity of reconciling logical processes with public sentiment and clamor. Changes, supported by local greed, may soon convert a sane national policy into a general "grab-bag" for distributing Federal funds to local projects, sometimes well conceived and involving important national interests, but too frequently badly conceived and purely local in character.

The cold statement of historical facts in regard to national enterprise may be interpreted as disheartening examples of "increasing feeding of local areas out of the Federal trough", or as examples of "the slow evolutionary assumption of Federal financial responsibility for undertakings of national interest." It is the writer's opinion that the correct interpretation lies somewhere between these two extremes.

Experience certainly teaches that before establishing any permanent national policy for financing public works, one should make certain, on the one hand, that the interests of the country as a whole are being adequately protected and advanced, and, on the other, that opportunities are not created for the complete degradation of local responsibility. The tendency, unfortunately, is generally in the latter direction, and safeguards must be provided in the water-resources development policy to avoid the error of expanding Federal power and financial responsibility without local responsibility.

It should be clear from this brief discussion of some of the financial problems involved that a trial-and-error technique is a pre-requisite to ultimate solution. Experimentation in government to-day arouses violent opposition in some quarters, but, carefully organized and carefully controlled, it appears to be a necessary adjunct to the normal processes of desirable water-resources development. A substitute for experimentation is no more desirable in this, than in any other scientific, field where rationalization has long since given way to trial-and-error technique.

More than fifty years ago, Ambassador Bryce made the discerning observation with reference to American political institutions, strongly applicable to the subject in hand, that: "The longer one studies a vast subject, the more cautious in inference does he become."

ADMINISTRATIVE ASPECTS

If future water development should result only from comprehensive study of possible multiple uses or methods, other problems beyond those of engineering and finance present themselves. Decisions must be reached from time to time as to what governmental or private agency should be permitted to undertake the construction of vast water-resources programs, whether for flood protection alone, or for multiple purposes. Controversy again rages in this field as between central and local public bodies and as between public and private agencies.

There are occasions, of course, when this particular administrative difficulty is absent. The development of flood-protection measures within Los Angeles County, California, alone, for example, may present no particular problems of national policy. The type of organization may be controlled locally. The methods of raising funds and assessments may be controversial, but, at the same time, not of national import. When the problem is extended, however, beyond the confines of a single county, or of a single State, and when the best uses of a stream include its development for power, for navigation, for potable water supply, and for flood protection, can some form of national control be avoided? The question is posed without prejudice at the moment. It should be brought clearly into the daylight, and its discussion should not rest wholly upon abstract and emotional concepts of political philosophy.

The administrative difficulties are not all resolved when the responsibility for the initial construction has been agreed upon. Similar difficulties arise in the operation and management of undertakings, where further reconciliation of diverging interests may be continually necessary.

Recent experience with one of the reservoirs in the Far West, is illustrative of a type of problem likely to be multiplied in the future. With a full reservoir, technical experts recommended, on the basis of snow surveys, that the reservoir be emptied so that its capacity would be available for catching spring run-off. If this had not been done the heavy spring run-off, equivalent to the reservoir capacity, would have created damaging floods. Yet compliance with this competent technical advice required extensive negotiations with political parties, private interests, and public agencies, leading ultimately to the Governor of the State for final decision. The engineer cannot ignore the brute facts of public pressure no matter how cloistered he may be.

History has shown that each drop of water may be the source of deadly conflict. The problems cannot be settled in the laboratory, but must be adjusted in terms of public demand. Undoubtedly, the Engineering Profession has the task of educating the public in the field of its operations. It is a task, incidentally, in which so far it has made no great progress; otherwise, the clamor for faulty engineering panaceas would not have reached the heights it has attained in recent years.

SUGGESTED APPROACHES TO THE DEVELOPMENT OF A NATIONAL WATER RESOURCES POLICY

No easy road to the promulgation of a national policy for flood protection or for a national policy of broader character is available. Acceptance of this conclusion has led agencies of all levels of Government, and the Water Resources Committee and its predecessors (the Mississippi Valley Committee and the Water Planning Committee of the National Resources Board), to approach the task experimentally.

The operations of the Miami Conservancy District, the Muskingum Conservancy District, the Corps of Engineers on the Mississippi Valley flood-control work, and of the Tennessee Valley Authority are all indicative of a distinct, although unconscious, desire to direct public action into logical engineering, financial, and administrative channels. The varied experiences of each of these organizations disclose a gradual evolution toward emphasis on multiple uses of streams, on drainage-basin concepts, on Federal-local participations, and on generally broader handling of stream problems than those current in the early years of the century.

Whether for better or worse, people are beginning to view the control of a stream for flood reduction as an integral phase of the use of that stream for power, navigation, irrigation, public water supply, and sanitation. To the writer it is an evolutionary step of merit. It creates complications in all fields of attack, but the objectives appear wise.

To the aforementioned approaches by Federal and local agencies, the Water Resources Committee has added several undertakings, which are briefly presented herein as further examples of multiple-use of streams. In its studies, the Water Resources Committee has kept two basic principles in mind: First, it has included in the deliberations on the uses of a particular stream, the States covered by the drainage basin in question (this was done on the assumption that no real progress in analysis or solution of the problem would be successful without the highest degree of local participation); and, second, it has assumed that no standard method of approach has yet been evolved, which is invariably applicable to the United States as a whole.

The Committee assumed further that different problems would require different structural arrangements for experimental demonstration, and that the cost of carrying out such experimental studies in every instance should be borne by the Federal and local agencies primarily concerned.

The Red River of the North.—The investigation of the Red River of the North resulted largely from a meeting called on June 3, 1935, in Fargo, N. Dak., by the Governors of Minnesota and North Dakota to consider the problems of water conservation, stream pollution, and sewage disposal in the Red River Valley. The call was directed particularly to the members of the State Planning Boards of the three States—Minnesota, North Dakota, and South Dakota.

This conference was followed by a second one in St. Paul, Minn., on November 26, 1935, in which representatives of the National Resources Committee participated. At this meeting, a committee was appointed to develop a co-ordinated plan for the development and protection of water throughout the basin of the Red River of the North. As representatives of the Water Resources Committee, W. W. Horner, M. Am. Soc. C. E., of St. Louis, Mo., and Harlan H. Barrows, of Chicago, Ill., were delegated to act. At the request of the conference, Mr. Horner was designated by the National Resources Committee as Technical Consultant in the preparation of the ultimate water plan.

On July 8, 1936, a report of the Third Inter-State Conference on the Red River of the North Drainage Basin was issued, proposing an adequately developed water plan, on a long-time basis, the primary objective of which is the development of dependable stream flows during the dry periods of the year in quantity ample for urban water supply and for the dilution of wastes. To attain this objective, the plan called for the development of storage in head-water areas, the regulation of stream flow in accordance with a predetermined program, and for improvement of stream channels to minimize water losses.

The report also reviewed the physical characteristics of the basin, its economic conditions and trends, and its water problems, and presented a recommended program of projects to put the co-ordinated plan of water development into action.

This is perhaps the first comprehensive program of river drainage basin improvement carefully developed in the United States, with three State groups participating and with competent engineering control and direction. It offers for the first time a skilfully drawn program for water conservation, susceptible to step-by-step construction in accordance with the financial capacity of the territory to carry the load. It provides for flood control in heavy run-off periods and for low-water supplementation in dry years.

The findings of the report are now (1937) being put into effect by local groups, and where money is being spent by Federal agencies in the territory, it is being spent in accordance with the definitely formulated plan.

The development of such a program implies time and the availability of money. It cannot be accomplished otherwise. The case in point illustrates, however, that it is feasible, with a certain amount of central direction and stimulation, to interest individual States in the preparation of a joint comprehensive program of action. It is hoped that this precedent may be followed with necessary local modification by other groups of States having similar pressing problems of water use. It is not implied, of course, that local pressures may not create deviations from the master plan, but the existence of an agreed master plan generally reduces these hazards to a minimum.

The Rio Grande.—Competitive uses of the water of the Rio Grande had reached such an acute stage in 1935 that it became necessary for the President of the United States to issue an order preventing the release of further Federal funds for any projects on this basin north of El Paso, Tex., until the National Resources Committee had approved the undertaking. An interstate compact between the States of Colorado, New Mexico, and Texas had been in operation for some time and was to expire in June, 1937.

In view of the conflicts of interest these three States, together with the Federal agencies concerned, undertook a detailed study of the water resources of the basin. Both Federal and State groups have contributed money and personnel to the undertaking. The studies should disclose noncontroversial bases for the development of new agreements. They may be substitutes for Court action and may lead to the evolution of interstate agreements for the use of the Rio Grande water without basic controversy. The method of approach is again one for special purposes which might be adopted in other areas. Again, time and money are pre-requisites; it should be emphasized that without these two elements programs and policies cannot be "pulled out of thin air."

Kansas River Flood Studies.—The first contribution to the study of the Kansas River flood problem by the Water Resources Committee, or its predecessors, was made on November 1, 1934, when $25 000 was made available for expenditure under the direction of the Chief of Engineers, U. S. Army, for survey and investigation of the Milford Reservoir site on the Lower Republican River and the Tuttle Creek site on the lower part of the Big Blue River. Before investigations were started, it was decided to hold up the work pending agreement with the Flood Protection Planning Committee for Greater Kansas City, in regard to the conduct of the study, and the appointment of a Consultant by the Committee. The agreement was soon reached, and the surveys went forward during the summer of 1935, with F. H. Fowler, M. Am. Soc. C. E., as the Consultant.

It shortly became aparent that a complete plan for reservoir control of the Kansas floods might require the construction of additional storage on tributaries entering the main stream below the Republican and the Big Blue, and that considerable information regarding flood conditions in Kansas City might be secured from a river model. On the recommendation of the Water Resources Committee additional funds were made available to the U. S. Division Engineer on November 27, 1935. These funds consisted of $22 500 for surveys and borings at supplementary storage sites, and $12 000 for a river model, which was later constructed at the U. S. Waterways Experiment Station, at Vicksburg, Miss.

During the spring of 1936, the Bureau of the Budget rescinded $8 000 of the $22 500, thus preventing temporarily the completion of the schedule of boring at the dam sites. However, shortly afterward, Congress authorized a preliminary examination of the Republican and Smoky Hill Rivers with a view to the control of floods, and the Flood Control Committee of the House of Representatives authorized the Corps of Engineers to review the Kansas River report already published[8]. As a result, $150 000 was made available to the U. S. Division Engineer for additional studies. Of this amount, $8 000 was used to replace the amount rescinded by the Bureau of the Budget. Two series of tests on the river model were completed at Vicksburg during 1936. The results have gone far toward remolding public opinion.

---

[8] H. R. Doc. 195, 73d Cong., 2d Sess.

Study of an alternative arrangement of levees, combined with bridges, was initiated by the U. S. District Engineer Office, in Kansas City, after a joint inspection by the U. S. Engineer and the Flood Control Committee in May, 1936.

The development of the final plan should represent the reconciled viewpoint of all interests. The method of approach illustrates the merit of joint review by the Corps of Engineers and the local Flood Control Committee and its engineer advisers.

Potomac River Conservancy District.—The Water Resources Committee in 1934 recommended to the President the establishment of a Potomac River Conservancy District, primarily for the purpose of providing a field laboratory for evolving engineering, administrative and financial principles, and methods of control. In this instance, as in others, the district was to be under the supervision of the interested States, with Federal participation in a minority membership on the commission. Financing of the enterprise was to be largely by local agencies, public and private, with the stimulation of the Federal Government. Its purpose is solely to develop methods of arriving at solutions on major drainage basins. No action had been taken on this proposal, as of March, 1937, but it is presented herein as another device for supplying the nation with additional information on the problem of drainage-basin control and development. It was proposed as a more practical alternative to nation-wide drainage basin authorities, for which the ground is not yet prepared and which only future careful study can demonstrate to be valid or invalid structures for drainage-basin operation.

The National Drainage Basin Study.—Most civil engineers are familiar with the drainage-basin study of the Water Resources Committee. Its purpose is to indicate the outstanding water problems in the various drainage areas of the country, to fit them tentatively into integrated patterns of water development and control, and to present, where existing data make it possible, specific construction and investigation projects as elements of an enlarged plan.

This study supplements and extends the work of the Mississippi Valley Committee of the Public Works Administration and the Water Planning Committee of the National Resources Board, which agencies have been succeeded by the present Water Resources Committee.

The study under the title of "Public Works Planning" was presented to the President by the National Resources Committee in December, 1936. The President forwarded it to the Congress of the United States on February 3, 1937. It is to be followed by the issuance of a volume containing the more detailed findings of the Water Resources Committee. The date of the publication of this latter volume is the early part of March, 1937.

For many basins, the plan contains relatively few construction projects, because of the lack of essential data. In others, fairly complete construction programs are already available. Obviously, none of the plans is either fixed or final. No one supposes that any long-term plan for any drainage area can be formulated, immediately, in detail, even if all requisite hydrologic data were available. The drainage-basin study, however, should result in a significant contribution "to the framework of an enduring, but adjustable national water plan." It should serve to arouse professional and lay interest in water resources integration, in the extension of these preliminary studies under local auspices, in emphasis upon multiple, rather than upon single-use, development of streams, and in relating water development more adequately to the entire economy of a basin.

SUMMARY

In this paper, the writer has attempted to show that the development of a National Flood Protection Policy should not be separated from that of a National Water Resources Policy in general; that the elements of such policy are highly complex; that they run the gamut of engineering, finance, and administration; that they are bound up with the problem of public prejudice and pressure; that the contributions of engineering thought are the key to the ultimate evolution of a national policy; and that such engineering contributions must be made on the field of battle and not in *vacuo*. In order to clarify some of the issues and to evaluate some of the procedures, local and Federal public and private agencies are collaborating in certain studies. As time goes on the results of these studies should disclose certain principles of action and should supply the basis for an ultimate national policy, changing in character, logical in administration, and as free from prejudice and greed as is possible in a world still fortunately consisting of human beings. A perfect syllogism of action is probably not attainable.

THE ECONOMIC ASPECTS OF FLOOD CONTROL

BY NATHAN B. JACOBS,[4] M. AM. SOC. C. E.

SYNOPSIS

Flood control is a problem of applied economics in which the social security and protection of life and property must be evaluated in balancing the annual savings from flood control against the cost of construction and maintenance. Floods damage the homes of those least able to bear the cost, who only live in the path of the inundation because financially unable to move elsewhere. No formula has yet been developed to apportion costs of such works satisfactorily between Government (Federal, State, and Local), and property owners, but each plan represents a problem for solution not only in its engineering aspects but also in distributing the costs.

INTRODUCTION

Engineers are guided largely by the principles of economics. Rigid rules are followed to test the economic worthiness of buildings, bridges, dams, railways, etc., before capital is called upon to make the projects possible. Heretofore, proposals for flood protection have been subjected to the same rigid analysis. Measurable direct damage is estimated and tabulated. To this is added some evaluation of the indirect damages that cannot be definitely determined. From this, the average annual damages incurred within and without the flooded areas, are determined. If the return on capital to be invested in protective works, plus depreciation, maintenance, and operating expenses, is less than the average annual damages sustained, the proposed project is considered to be on a sound economic basis.

It is true that flood control involves questions of economics, because floods destroy wealth and property, disturb the production and exchange of goods, and endanger lives and health. The questions, however, are not so much those of pure economics as applied economics—the science that seeks the improvement of existing conditions and the translation of such knowledge into action. Should a strictly monetary evaluation be the only basis of providing relief from inundation by waters gone wild?

SOCIAL SECURITY A FACTOR IN EVALUATING FLOOD CONTROL

Widespread human suffering and appalling loss of life have a stronger universal appeal than the monetary and property damage suffered by industry, trade, and transportation in major catastrophes. As far back as 1882, President Chester A. Arthur, in a message to Congress, stressed the sufferings of the people of the Mississippi Delta. A former Governor of Louisiana, the Hon. John M. Parker, felt the principle of humanitarianism to be so important that he maintained it to be inhuman to permit three-quarters of a million people to be driven from their homes and made dependent upon the charity of fellow Americans. In 1927, former President Herbert Hoover, Hon. M. Am. Soc. C. E., then Secretary of Commerce, in discussing the 1927 Mississippi flood, said the losses sustained touched the entire nation, and subtracted something from the wages or income of every citizen.

---

[4] Pres., Morris Knowles, Inc., Pittsburgh, Pa.

The concept of humanitarianism is forcibly brought to public attention by the wording of the Omnibus Flood Bill, enacted into law in 1936 by the 74th Congress of the United States. This law reads, in part:

"That the Federal Government should improve or participate in the improvement of navigable waters or their tributaries, including watersheds thereof, for flood control purposes if the benefits to whomsoever they may accrue are in excess of the estimated costs, and if the lives and social security of people are otherwise adversely affected."

It will be noted from this passage that as the law now stands there are other considerations to be reckoned with than money or property damage. Under this Act, it is proper for the Federal Government to participate in flood-control projects if the life or social security of the people is in danger. This criterion will be as controlling and persuasive as the financial formula by which it formerly was necessary that projects be economically justified on the basis of past experience. There is inculcated in the minds of this generation, more so than in those of the past, a higher regard for general welfare and human protection.

The construction of flood-protection projects on a monetary economic basis alone is a thing of the past. Where the lives of human beings are endangered and where great suffering may occur as a result of floods, protective works should be constructed. It is too much to expect that people shall move from the path of danger.

In 1906, there occurred one of the worst catastrophes in the history of the United States—the San Francisco earthquake—which rendered 25 000 homeless and caused monetary losses estimated at $600 000 000. The people of that city had the courage to rebuild on the same site, with the knowledge that no man-made protection could be afforded. Human nature is the same the world over, and cities ravaged by floods have been rebuilt just as San Francisco was. It seems to be the spirit of some to reside in danger zones. The fact that floods occur again and again has not acted in the past, and will not act in the future, as a deterrent to the rebuilding of homes and the re-establishment of commercial enterprises and industries in perilous localities. Since it is possible to provide measures of protection against floods, the people who live in flood-plains must be afforded that protection.

Furthermore, the returning to homes, or to the location of former homes, after a flood disaster, may not be so much a matter of choice as of compulsion. City planners claim that much of the territory that is inundated during a flood is not economically and practically adaptable for homes, and that, therefore, the proper procedure is to relocate these families on ground reasonably above the flood-plain. In large cities, however, many of the commercial and industrial enterprises are located as near the river as possible, often for the purpose of obtaining water for condensing or cooling purposes; and many workers live in homes near the industries because of the convenience and economy of being able to walk to work in a short time. Although transportation is now much more readily available and more economical than formerly, the workers continue to live in these houses, possibly because there are no other houses available in the district.

For example, of the area in Pittsburgh, Pa., that was inundated in the flood of March, 1936, about 80% is zoned as "heavy industrial." Under the provisions of the zoning ordinance, no residence may be built in a heavy industrial district. Of course, the law is not *ex post facto*, and residences existing in such a district at the time of its passage (1923) were permitted to remain. However, it may be assumed that no new dwelling has been constructed in the heavy industrial zone since that time, and, further, that no house has been subject to major repair, because permits could not be obtained for either purpose. Many of the houses in the district have already been condemned by the Pittsburgh Housing Association as not fit for human habitation. During the flood, the Association made provisions to prevent tenants from returning to these condemned houses after the water receded; but as homes within the rent range of these tenants were not available in other and higher parts of the city, it was necessary, in order to re-house them, to allow them to return to their original homes. Such a condition may be alleviated by additional housing and proper city planning and zoning, but it cannot be cured.

ENGINEERING ASPECTS

The economic problem of flood control does not have a single answer, such as the solution of an algebraic equation. There are many ways to reduce flood damages. Retention basins, storage reservoirs, levees, channels, and dikes are the common structures provided. The problem is not so much one of design and construction as of determining the most economical type of protective works. This requires a competent and comprehensive engineering study. A comparison of the initial cost of construction of the various plans on the same price basis is necessary. Annual charges must be compared against the average annual benefits to be derived, in order to determine the most economic project. Consideration must also be given to the degree of protection afforded by each plan, as the human and social welfare angle must not be ignored. It is also essential that those who must pay for the protective system have full knowledge of the cost, of what burden they must bear, and of what security the final developed plan provides.

The physical characteristics of the up-stream basins will have considerable bearing upon the plan to be selected. In some localities, sites for retarding dams may not be available. In others, the construction of the dams may be economically impossible; good borrow-pits may not be available for the construction of earth dams; and concrete masonry structures might prove to be far too costly. If the river traverses wide, flat lowlands, levees and channel improvements may be the best solution. In the adoption of any flood-control plan, it should be emphasized that floods cannot be prevented. Protection against all floods will not be furnished by a control system; no one can predict the intensity of the maximum flood to come, but the damage caused by floods of certain heights can be reduced or entirely prevented, and that fact should be stressed by the promoters and designers of projects.

In the matter of design and operation of works to impound flood waters, there are two schools of thought. One holds that such reservoirs should act solely as retention basins, and be automatic in control. Others advocate reservoirs that may be used for many purposes, such as storage for power and water supply and for regulation of the stream during periods of low flow. The degree of flood protection desired establishes the basis for the selection of retention, or multi-service, reservoirs. Multi-service reservoirs may not provide maximum flood control, because rapid and heavy run-off may occur when they are full or nearly so. One or more of the services to be rendered by this type of reservoir must suffer because of the others. On the other hand, if automatically controlled retention basins are constructed, future conservation of water for other uses will be seriously hampered.

Examples of both methods of control are in service. The automatically controlled retention basin is best typified by the reservoirs in the Miami Conservancy District of Ohio. The more recently established Muskingum Watershed Conservancy District, in the same State, provides for protection against floods, by three automatic retention basins and eleven multi-service reservoirs. The Sacandaga Reservoir, constructed in 1930, in New York State, is an example of the multi-service type. It is operated as a storage reservoir to regulate the flow for power interests down stream. At the same time, it acts as a retarding basin to some extent, thereby lessening flood heights of the Hudson River, at Albany and Troy, N. Y.

Another typical multi-use reservoir is the one on the Tygart River, in West Virginia, which was designed primarily to aid navigation on the Monongahela River, but which can and will be used for flood-control purposes as well. It is planned to operate this reservoir so that it is empty near the end of December; from then until April 1, a volume of 100 000 acre-ft of water will be allowed to accumulate. This volume will be drawn on as required during the remaining nine months of the year to assist navigation. Flood water will be impounded during January, February, and March, thus reducing flood heights on the Monongahela River.

The Pymantuning Reservoir, on the Shenango River, in Pennsylvania, was designed primarily for low-water control and for recreational purposes. Since its completion in 1933, however, it has been responsible for lowering flood heights at Sharon, Pa., and other communities. (The reservoir was completed in June, 1933; the project was completed and the gates closed on January 23, 1934.)

The first and foremost thought in providing flood-protection projects should be to obtain maximum security. It is conceded that many multi-service projects are worthy; but if flood protection is the major problem of the community, it should not be sacrificed to the benefit of other uses. On the other hand, if the amount of protection desired permits the use of multiservice reservoirs, these projects should be erected, in order to further the conservation of water as a natural resource. Such reservoirs could be constructed initially for flood control, with provisions for the future installation of power units where they appeared feasible.

The Distribution of Costs

The furnishing of needed funds for flood-protection works is a controversial question. Should flood protection be considered a problem of local interests alone, or should Municipal, State, and Federal Governments share in the cost? Those who live within the flood path do not consider the cost of protective works to be a local problem. It is their contention that the entire cost, or the greater part of it, should be borne by governmental agencies outside the affected area. On the other hand, those who are not directly affected object strenuously to contributing to the cost. Flood disasters, however, have far-reaching effects and, indirectly, the entire nation suffers to a greater or less degree.

Following severe and damaging floods, there generally occurs in the inundated area and surrounding territory a depreciation in property values because of the slowing up of business activities. This is due to the hesitation of industrial organizations and individuals to locate in the community. Losses occur outside the flooded area through the disruption of electric service, water supplies, communication, transportation, and other utility services. The commodity market is disturbed, and prices rise. Counties, towns, and cities are losers to the extent that municipal property is damaged, and also to the extent that depreciation of private property reduces the value upon which taxes can be assessed Floods also cause a loss to the Federal Government, especially where navigation is affected; lock-gate machinery is damaged, erosion takes place around wing-walls, and costly re-dredging of channels is necessary, where silt and débris have been deposited by excessive flows.

The distribution of the cost of a flood-control project among the beneficiaries is a difficult problem. Should the Federal Government bear the entire cost, one-half the cost, or a lesser amount? What should be the share of State and Local Governments, and how should private interests and those immediately affected contribute toward the cost?

Flood-control works have been financed in various ways. The Pymatuning Reservoir, previously referred to, was paid for entirely by funds appropriated by the Commonwealth of Pennsylvania, except for certain land and flowage rights in Ohio, which were acquired by the industries and other interested parties in the Shenango and Beaver Valleys, and donated to the Commonwealth. No doubt the legal difficulties created when one State acquires property in another, prompted this action. In the case of the Sacandaga Reservoir, in New York State, almost 95% of the cost was assessed directly against the water-power properties benefited by the river regulation. Although the project has been of value to navigation and has provided flood protection, only 5% of its total cost has been borne by the public in general.

The Miami Conservancy District System was constructed at a cost of approximately \$30 000 000, without Federal or State assistance. This entire investment will ultimately be repaid by the interests benefited, about one-half by direct assessment on property in the district, and the remainder through tax levies. Of the total direct assessments, 5% is levied on farm lands, and 95% on city and industrial property.

The Muskingum Water-Shed project is being financed in a different manner. The total estimated cost of the work is given[5] as \$34 590 000. Of this amount, \$22 590 000 is to be furnished by the Federal Government from funds of the Public Works Administration for construction purposes. This contribution includes two elements: First, the PWA grant; and, second, the payment for Federal benefits. At the time the project was begun, the estimated construction cost was \$22 000 000. On this basis the PWA grant (30% of construction cost) was \$6 600 000. However, a study was made of the navigation benefits and the savings in future construction work for navigation projects on both the Muskingum and the Ohio Rivers. This benefit was due to the stabilization of the stream flow. Credit was also given for the lesser interruption to river traffic at times of flood level. Federal participation, due to the reduction of flood crests and the benefit to navigation, was computed at \$15 990 000, making the total Federal contribution to the project \$22 590 000. The State of Ohio participated on the basis of the protection afforded State property, including highways. In regard to the latter, it estimated that the benefits would be greater than the cost of the relocations made necessary by the construction of the reservoirs, and, therefore, permitted the Highway Department to co-operate with the Conservancy District in the relocations. The State Legislature further made a direct grant to the District of \$2 000 000. The remainder of the fund, comprising the total cost of approximately \$34 500 000, is being made up by the District itself through assessments on benefited properties, and taxation in the District.

The Miami Conservancy District is a more heavily industrialized area than the Muskingum District, and, therefore, it no doubt could bear better the burden of providing the entire cost without aid from State or Federal Government. Conditions exist throughout the country, however, where the affected area will not be able to bear the entire cost of protective works. This is especially true in agricultural areas.

In making an equitable distribution of the cost of flood-control projects, both direct and indirect benefits must be estimated. The total cost should then be apportioned among the various interests in accordance with the benefits. The percentage of the cost to be borne by each group cannot be set by any given formula; it should be determined in each individual case on the basis of the problems involved.

The formula for Federal participation in the cost of flood control, as set up in the Flood Control Act of 1936, is sufficiently discussed by Lt.-Col. Covell.

---

[5] "The Muskingum Flood Control Work": A Symposium, *Civil Engineering*, January, 1936, p. 1.

Whatever may be the basis of cost distribution, it is essential that the full cost of the project be established. It should also be broken down to reveal the cost of land, rights of way, structures, equipment, and all other major elements, not only so that these costs may be distributed among the beneficiaries, but also to permit the etablishment of correct depreciation rates on the various projects.

Benefits of Flood Control

Alleviation of major floods will undoubtedly improve the productive efficiency of the affected areas. When all industry and trade are stopped by flood, it requires weeks, or months, to restore them to normal operating capacity. While repairs are being made, disrupted organizations cannot concentrate upon their normal activities. Their efficiency is lowered, with the result that not only they, but their clients and customers also, suffer to some extent.

With flood-control systems installed, rail and river transportation systems will be free of their worst enemy, and the keeping of transportation systems in a state of efficient operation not only benefits local interests in the flooded area, but also the nation as a whole. Particularly would this be so in case of war. Had the 1936 Pittsburgh flood or the 1927 Mississippi Valley flood occurred in time of war, carefully timed shipments of supplies and materials to the seaports would have been seriously delayed. If the country had been involved in repelling an invasion, the hampering effect of the floods on the efficiency of the military organization might have been even more serious.

The highway system is just as important as the railroad and navigation systems, and flood-protection work will enable the construction of more dependable highways throughout the flooded areas. Airways, too, will be benefited in many cases by the possibility of establishing terminals nearer to the centers of large cities.

If transportation systems do not suffer recurring flood damages, maintenance charges will be reduced, and the money thus saved will be diverted to other and more productive channels.

Floods have done a vast amount of damage to agricultural lands. Whenever crops are destroyed, the loss is felt not only by those directly damaged, but by all who buy the products of agricultural industry. With less soil erosion in these agricultural districts, the farmer will be able to produce his crops without fear of their being washed away; and the improvement in his economic status will be a gain not only for him but for the entire community.

One of the most serious consequences of a disastrous flood is that, in so far as residential properties are concerned, it affects adversely those people who are least able to bear the burden. As previously stated, 80% of the property in Pittsburgh inundated in the 1936 flood was "heavy industrial", but thousands of people lived in this territory. They had not the wherewithal generally to move into better districts. Much of their income must go for replacing and restoring damaged properties. Incidentally, this reduces the demand for consumer goods, particularly food and raiment, and thereby creates further economic maladjustments. Most of this could be avoided by proper provisions for flood control.

There are many other benefits of flood control that might be mentioned here. The danger of interruption of the water supply of river towns will be materially reduced. The value of industrial sites along the river plains will be increased, and better housing facilities can be constructed in their vicinity. Recreational facilities, such as parkways and parks along rivers, can be developed. Rural communities and business enterprises which depend upon tourist trade will profit through the prevention of stream erosion. The artificial lakes created by multi-service reservoirs will themselves provide a source of outdoor enjoyment that is rapidly becoming an important part of American life.

FLOOD CONDITIONS IN NEW ENGLAND

By W. F. Uhl,[*] M. Am. Soc. C. E.

Synopsis

In New England there have been two disastrous floods within the past nine years. The losses due to the flood of November, 1927, are estimated at about $40 000 000, with nearly two-thirds of this in Vermont.

With the estimates virtually complete (February, 1937), the damages due to the March, 1936, flood amount to about $70 000 000, of which $55 000 000 occurred in the Merrimac and Connecticut River Valleys alone.

The problem of preventing or lessening of damages to all kinds of property during floods has received consideration throughout the ages and many solutions have been proposed.

There is no complete practical solution but numerous partial solutions can be offered. Many of these are suitable only where peculiar conditions make them practical. Even where there is a practical solution, it may be not be economically feasible.

In New England, one of the methods which appears economically feasible is to build reservoirs designed for storage, which afford a large measure of flood protection as a by-product.

The statistical data collected on the 1927 and 1936 floods have materially increased the information available on the magnitude of flood flows.

Introduction

Most of the older cities situated on the rivers of New England have developed their present facilities and industries during the last 100 yr. Many of the important water-power centers have experienced their complete development during this period. Previously, floods, although undoubtedly causing much inconvenience, did little damage, as indicated by a lack of historical data regarding them.

Under existing conditions, with large and important cities and their various utilities situated in the river valleys, the flood hazard is becoming more serious and the economics of flood control are being investigated.

It is unfortunate that the records of the behavior of New England rivers are so meager, and it is of increasing importance that all available information be collected, recorded, and properly interpreted for future use in connection with possible mitigation of flood hazards.

---

[*] Hydr. Engr., Chas. T. Main, Inc., Boston, Mass.

TOPOGRAPHY OF NEW ENGLAND

The topography of New England is dominated by the two northern ranges of the Appalachian Mountains, the Green Mountains, which practically divide the State of Vermont in two, and then extend across Western Massachusetts into Northern Connecticut as the Berkshire Hills; and the White Mountains, which occupy most of Northern New Hampshire and extend half-way across Northwestern Maine. The general level of these mountains is between 1 000 and 2 000 ft, with some areas above 2 000 ft and the mountain peaks considerably higher.

Five of the largest New England rivers rise within a 50-mile radius in the White Mountains: The Kennebec (drainage area, 5 970 sq miles), the Androscoggin (3 470 sq miles), the Saco (1 720 sq miles), the Merrimac (5 015 sq miles), and the Connecticut (11 320 sq miles). Speaking very generally, each of these water-sheds may be divided into three parts, as follows:

(1) An upland area, where the rivers move sluggishly through plateaus containing a large number of lakes. Valuable storage has been created in many of these lakes by the construction of dams at their outlets. The Rangeley System, on the Androscoggin River, and the Moosehead Lake System, on the Kennebec River, are the most notable examples of this.

(2) A central part, characterized by steep slopes and narrow valleys on the main rivers. Many of the tributaries entering this stretch come off the mountain sides, and are very flashy.

(3) A lowland area in which the slope of the rivers is less pronounced, but more concentrated by ledge barriers. Above these barriers, the valleys widen out, and the banks are low, so that in time of flood large amounts of channel storage space become available. It is at the ledge barriers that the valuable early water powers, such as Holyoke, Mass., Lowell, Mass., and Lewiston, Me., were developed. The tributaries in this stretch are generally sluggish, with practically all the available fall and some storage developed.

The Penobscot River (drainage area, 8 570 sq miles), the largest in Maine, rises in the mountains east of the head-waters of the Kennebec. Compared to the other Maine rivers the level upland part is larger and the water-shed wider in proportion to the length. Natural lakes and reservoirs are scattered over the entire drainage area.

West of the Connecticut lies the Housatonic River (drainage area, 1 930 sq miles), which rises in the Berkshire Hills and flows south across Massachusetts and Connecticut. This river is relatively flat, with a wide valley affording much channel storage in times of flood. The amount of developed storage is small.

The west slope of the Green Mountains is drained by the four Vermont rivers which are tributary to the St. Lawrence River by way of Lake Champlain: Otter Creek (the farthest south), the Winooski, the Lamoille, and the Missisquoi, the drainage areas being 925, 1 076, 710, and 885 sq miles, respectively. Otter Creek is the flattest and most sluggish, with some natural storage in the numerous marshes and flats. The other three streams to the north are more precipitous, with very little storage, either natural or developed.

THE 1927 FLOOD

The floods of November, 1927, and March, 1936, are outstanding events in the recent history of New England. The two floods, both of which exceeded all previous records in their respective sections, were caused by altogether different climatological combinations.

FIG. 1.—RAINFALL IN NEW ENGLAND, NOVEMBER 3 AND 4, 1927.

The 1927 flood was much more localized than the 1936 flood. The worst of the damage was confined to the State of Vermont, with spectacularly high flows occurring on drainage areas of 1 000 sq miles or less.

On the other hand, the effect of the 1936 flood was felt over most of New England, the areas least affected being the State of Vermont and Northern Maine. It was on the large rivers that the record-breaking flows occurred. Although the total damage in the 1936 flood was about twice as great as in 1927, the devastation wrought by the 1927 flood was much more intense in the localities affected, and the loss of life was much greater.

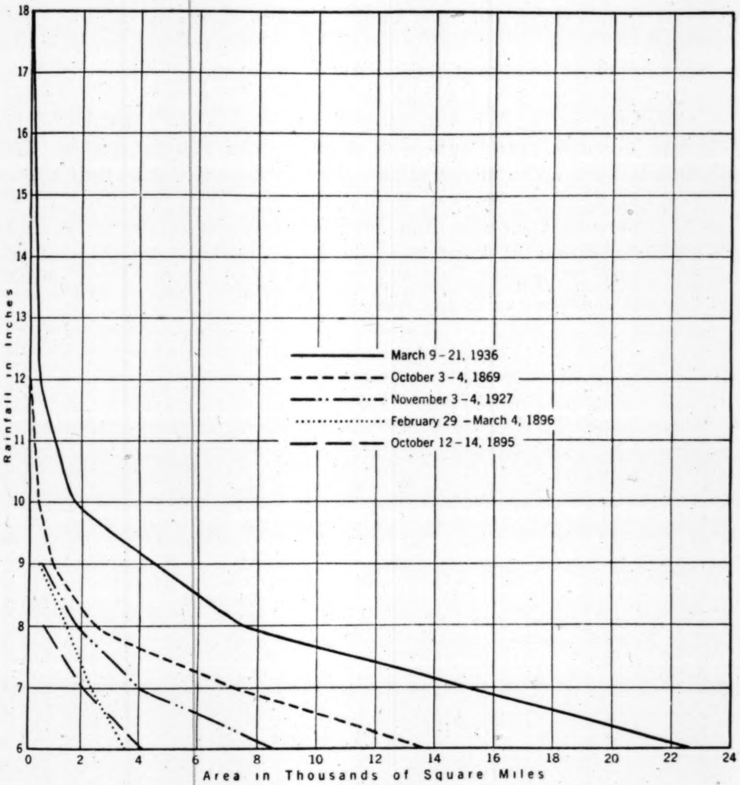

Fig. 2.—Rainfall-Area Relation for Great Storms in New England

The November, 1927, flood resulted from the torrential rains produced when a tropical storm, coming up from the South, was caught between and forced over two cold areas of high pressure, one moving in from the northeast and another from the northwest. When this storm began, the ground was still saturated from the heavy rains of October 18 to 21; the surface storage had been largely utilized; and the rivers had already risen to medium stages.

The rainfall which produced the 1927 flood occurred almost entirely on November 3 and 4 (Fig. 1). The precipitation was greatest in Vermont, with the maximum recorded at Somerset (Elevation 2 080), in the southwestern part of the State (9.65 in. in two days). It is probable that 11 to 12 in. fell in the higher portions of the Green Mountains. Another area of high rainfall was centered near the Rhode Island–Connecticut State line. The 2-day rainfall exceeded 9 in. over an area of about 500 sq miles, 460 of which was in Vermont, in the Green Mountains, and 40 in Rhode Island and Connecticut. The rainfall exceeded 5 in. over an area of about 22 000 sq miles, or one-third the area of New England. Data on the rainfall-area relations of this storm and other great storms in New England are plotted on Fig. 2.

As a result of this great precipitation, the rivers quickly rose to flood stages on November 3 and 4 and filled many of the valleys. Excessively high velocities on the rivers with steep slopes, such as the Winooski and the White in Vermont, caused sudden flood peaks which arrived at night. The inhabitants were taken unawares and many were drowned in their houses. In Vermont, 87 lives were lost, 55 of them in the Winooski River Valley. The total property damage in New England was about $40 000 000, of which $26 000 000 occurred in Vermont. This was equivalent to 3.27% of the taxable wealth of the State in 1920, or $74.30 per capita. About one-half the loss was concentrated in the Winooski Valley.

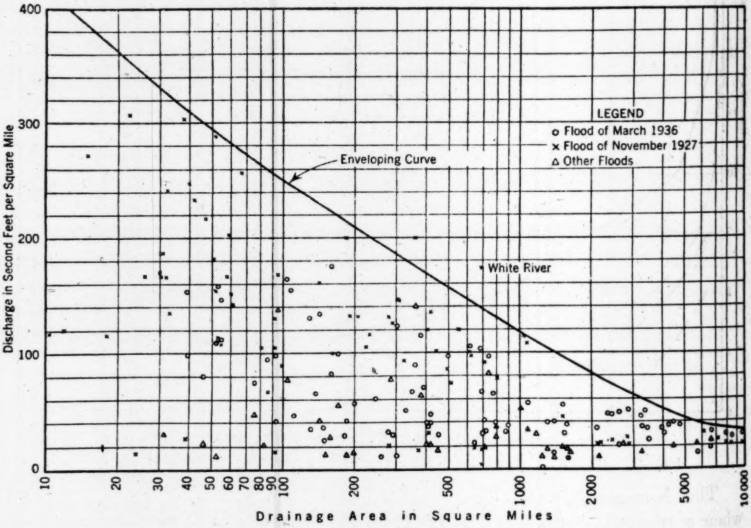

FIG. 3.—PEAK FLOWS OF NEW ENGLAND STREAMS

On the Winooski River, a flow of 116 000 cu ft per sec was observed, equivalent to 114 cu ft per sec per sq mile. On the White River, which drains the eastern slope of the Green Mountains and is tributary to the

Connecticut River, a flow of 140 000 cu ft per sec was observed, equivalent to 202 cu ft per sec per sq mile. These two flows are still (February, 1937) the maximum of record in New England for drainage areas of comparable size. On smaller drainage areas, much greater discharges per square mile were observed. Many of the 1927 flows are given in Table 3, and are plotted on Fig. 3.

The flood of November, 1927, has been described so thoroughly in the report of the Committee on Floods of the Boston Society of Civil Engineers[7] and by H. B. Kinnison, Assoc. M. Am. Soc. C. E.,[8] that further comment regarding it will be restricted to a comparison with the 1936 flood.

The 1936 Floods

The March, 1936, floods were due to an aggravated combination of the conditions that normally cause the annual spring freshets in New England. The fundamental cause was, of course, the abnormally high precipitation in a period of unseasonably warm weather which quickly melted the heavy snow cover. The first storm, March 12 and 13, melted most of the snow and produced flows considerably greater than the usual spring freshet. After a lull, with the rivers bank-full but receding, there came three more days of unusually heavy rain which fell on ground largely bare and frozen, with all the low spots full of water. Practically all of this second storm went rapidly into the streams and built up record-breaking flows. The excessive rainfall was the primary reason for the flood, but various other factors contributed largely to the eventual result.

Climatological Conditions Prior to the 1936 Flood.—In general, the winter of 1935–36 in New England was one of about average precipitation, but lower than average temperature. For New England as a whole, the average temperature for December, 1935, and January and February, 1936, was 20.6°F, which is 3.2° below the mean temperature for these months. This deficiency applied about equally to all six States.

The total precipitation for these three months was 10.32 in., which was 0.41 in. above the normal. The total snowfall, to March 1, as recorded by a number of stations, was 35 in. in the Southern States and 64 in. in the Northern States, or about 5 in. above normal.

The winter was a severe one, characterized by long-continued periods of sub-freezing weather, with few thaws. Data collected by the power companies and winter sports organizations indicate that by March 1 the snow cover in Northern New England was about 2.5 ft thick, with perhaps a foot more in the mountains; in Southern New England, it was from 1 ft to 2 ft thick.

During most winters the snow blanket in Central and Southern New England lies in layers of crust and powdery snow, due to the alternate periods of freezing and thawing. In the winter of 1935–1936, however, the snow came early, and because of the lack of thawing weather the blanket was light and powdery throughout its depth, which made it much more susceptible to quick run-off than usual.

---

[7] *Journal*, Boston Soc. of Civ. Engrs., September, 1930.

[8] "The New England Flood of November, 1927", *Water Supply Paper 636-C*, U. S. Geological Survey.

From March 1 to March 10, conditions were generally normal, with one hard freeze on March 2. On March 3, there was a moderate snowfall, adding

FIG. 4.—RAINFALL IN NEW ENGLAND, MARCH 11–13, 1936

a few inches to the existing snow cover. On March 9 a rise in temperature to above normal began, coupled with a light snowfall in Northern New England and moderate rain in Southern New England, on March 9 and 10.

Heavy rain began on March 11 and continued on March 12 and 13. The area of greatest precipitation centered in the White Mountains (see Fig. 4). The maximum rainfall in the 3-day period amounted to 7.78 in. and was reported at the Pinkham Notch Station, which is on the northeast slope of Mt. Washington, virtually on the divide between the Saco and Androscoggin water-sheds. In the same period, the water equivalent of the snow cover that melted in the vicinity of this station amounted to about 3 in. During this storm the rainfall was 7 in. over an area of about 70 sq miles, 6 in. over 450 sq miles, and 5 in. over 1 400 sq miles.

This precipitation was accompanied by an inrush of warm air from the Gulf, causing abnormally high temperatures which melted most of the snow cover in Southern New England and a part of that in Northern New England.

The daily record of maximum and minimum temperature, rainfall, and the quantity of snow cover at eight typical stations in New England are given in Table 1. The quantity and extent of the precipitation is also shown in Table 2, which gives the daily rainfall for twenty-six stations. Only those stations were included which had a record of snow depletion for the period. For each station the water equivalent of the snow depletion has been added to give the total equivalent precipitation during the period.

The combination of rainfall and melting snow resulted in a flood peak of major proportions on March 13, which carried a heavy ice burden. This flood is comparable to those which may be expected once in about every twenty-five years. The ice, being hard and strong, caused much damage to river structures, and in many cases to buildings located on the banks. Serious ice jams also formed on some of the rivers, causing severe valley flooding. In some instances the ice jams acted as diversion dams, causing new river channels to be cut.

The first flood had largely passed down the rivers by March 16, but some rain continued to fall afterward. Then a storm reached New England on March 18 and 19, giving rise to the record-breaking flood of March 19. This storm resulted from the junction of a moderately strong low-pressure area from the Gulf States with another low area coming from Indiana. The former caused an inflow of tropical and marine air which moved slowly to the north and east and reached New England on March 18.

In the second storm, March 17–19, inclusive (see Fig. 5 and Tables 1 and 2), the rainfall was much greater than in the first storm. The area of greatest precipitation was again the White Mountains, and the Pinkham Notch Station again reported the maximum precipitation, 10.76 in. The water equivalent of the snow cover which melted at this station was about 4 in., making a total equivalent precipitation of about 15 in. The rainfall was in excess of 8 in. over an area of about 300 sq miles, and in excess of 5 in. over about 1 000 sq miles. There was also about 5 in. of rainfall over 600 sq miles in Central Massachusetts not included in the areas mentioned in the previous sentence.

Another intense low-pressure area from the Ohio Valley followed on March 21, closely after the southern storm, causing heavy rains in certain sections

FIG. 5.—RAINFALL IN NEW ENGLAND, MARCH 17–19, 1936

The precipitation for the entire period, March 9 to 21, inclusive, was considerably greater than the sum of the precipitation during the two principal storms (March 11 to 13, and March 17 to 19), as at many stations there was some rainfall almost every day. The total rainfall at Pinkham Notch was 21.79 in. The entire snow cover at this station, 30 in. (with an estimated rainfall equivalent of 7.5 in.), melted during the period, making a total equivalent precipitation about 29 in.

The general pattern of the isohyetal lines for the period is similar to that for the two individual storms. The area of greatest precipitation centered in the White Mountains near Mt. Washington and ran across the head-waters of the Merrimac, Saco, and west central portion of the Androscoggin water-shed in a roughly elliptical shape with the axis from northeast to southwest. The 10-in. isohyetal line encloses two large areas: One, of about 1100 sq miles, in the White Mountains; the other, of about 600 sq miles, in the Androscoggin water-shed, with its center at Rumford, Me. The 10-in. isohyetals also enclosed a smaller area in Central New Hampshire, centering on the southeastern end of Lake Winnepesaukee, and another in Central Massachusetts, near Worcester. The extent of the rainfall for the period, March 9 to 21, inclusive, as compared with other great storms in New England, is shown on Fig. 2.

As one of the causes of the flood, the melting snow was next in importance to the rainfall. Data on the quantity of snow that melted, and on its water equivalent, are not nearly so complete as those on precipitation and temperature.

On the Connecticut River water-shed, an extensive survey of the snow cover and its water equivalent was made about March 1. Airplane views of the Connecticut Valley taken between March 21 and 24 indicate that by that time the snow cover was gone from the principal river valleys to within about 50 miles of the Canadian border.

On the Androscoggin River water-shed an excellent series of periodic observations of the snow cover and its water equivalent was taken in connection with the regulation of the storage. A similar set of observations, although not so extensive, was taken on the Upper Kennebec water-shed.

Scattered observations made in other parts of New England agree fairly well with the results in these three river valleys and indicate that, in general, except in Northern New England, the snow cover was equivalent to about 25% moisture; in other words, 4 in. of snow was equal to 1 in. of water. In the Upper Androscoggin and Kennebec River water-sheds the snow was heavier, with a higher moisture content. Observations made in this region about March 1, showed moisture in the layer of snow near the ground, indicating that the ground was frozen little, if at all, in this locality.

Fig. 6 is based largely on data from the stations listed in Tables 1 and 2. The lines show the sum of the rainfall and the water equivalent of the snow cover which melted between March 9 and March 21. The general pattern of these lines is similar to that of the isohyetals of Figs. 4 and 5. The 10-in. line includes about one-half of New England.

An examination of the climatological data for the entire month of March, 1936, shows the abnormality of the conditions which produced the floods.

Based on 98 stations, which cover the entire area of New England, the average temperature for the month was 38.9°, which is 6.5° above the mean for March for the past 49 yr, and higher than the average temperature for

FIG. 6.—TOTAL RAINFALL PLUS WATER EQUIVALENT OF SNOW DEPLETION IN NEW ENGLAND, MARCH 9–21, 1936

March in every year of that period except 1903 and 1921. Based on 178 records, the average precipitation for March, 1936, was 8.04 in., which is 4.66 in. greater than the mean for the past 49 yr, and greater than any March on record, and most of this precipitation occurred during the period from March 9 to 21, inclusive.

Extent of the 1936 Flood.—In most of New England the 1936 flood exceeded all existing records for high flows. The areas in which the flows were not unusually great were Vermont and Northern Maine.

On most streams the flood had two peaks, the first reaching a maximum on March 13 and 14, and the second and greater flood reaching a maximum on March 19 and 20. On certain rivers there was a third peak much lower than the other two, on March 22 and 23. The first peak has frequently been called the "ice flood" because of the damage inflicted by floating ice.

More data are available on the 1936 flood than on any previous one. The 1927 flood made New England "flood conscious" and, in addition, before the 1936 flood, governmental and State agencies were actively studying flood control, water storage, and stream pollution. Furthermore, private agencies, the utilities, and the water power companies, have always been active in the collection of pertinent data. Thus, when it was evident that a major flood was happening, all these agencies united to obtain as many data as possible. As soon as the flood had subsided sufficiently to permit it, parties were put in the field to continue this work. Particular mention should be made of the U. S. Geological Survey force which, laboring under great difficulties, made current-meter measurements at or near the peaks at many stations, thus obtaining definite measurements of the higher flows and providing data for the extension of rating curves.

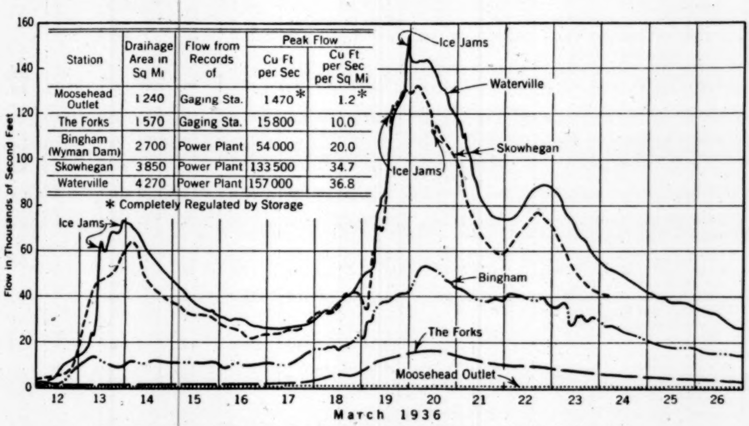
The 1936 flood peaks are given in Table 3, together with data on previously recorded maximums. This tabulation covers all the important rivers in New England, with special emphasis on those in which the 1936 flows were high. In addition, Table 3 includes the total run-off, in inches, where the data are available. The run-off has been computed in all cases for the period, March 12 to 26, inclusive, which seems to be the best average flood period on the various rivers. A consideration of the total run-off demonstrates the magnitude of the flow. The mean annual run-off of the larger New England rivers is about 22 in. In many cases, the total run-off for the 15-day flood period was as much as 9 in., or about 40% of this amount.

From the records of the U. S. Geological Survey and from those of the power companies, flood hydrographs have been plotted for significant points on the Kennebec, Merrimac, and Connecticut Rivers.

Kennebec River.—The hydrographs of the Kennebec River, in Maine (Fig. 7), cover the length of the main river, and are also well spaced as to drainage areas. The first flood peak, of March 13 and 14, was a "down-river" peak, and was produced by a moderate rainfall plus temperatures above freezing which melted a large portion of the snow cover on the lower water-shed. This peak was accompanied by ice jams from Bingham to tide-water at Augusta, and there were further ice jams on March 14 in the tidal part of the river all the way to the mouth. The ice jams were the occasion of much of the damage. The effect of an extensive ice jam in the river above Waterville is indicated on the Waterville hydrograph of March 13.

The peak of this first flood at Waterville, 71 500 cu ft per sec, was not great in terms of the entire water-shed, but from the 1 670 sq miles of intervening drainage area below Bingham, the peak was about 42 000 cu ft per sec, or 37.1 cu ft per sec per sq mile.

In the second flood there were further ice jams, which were caused by up-river ice. These jams can be observed in the Waterville and Skowhegan hydrographs. One of them broke and passed Waterville at 1:45 P. M., March 19, and reached the Augusta Dam at 4:40 P. M., traveling a distance of 20 miles in 3 hr. The peak of the second flood at Waterville, of 157 000 cu ft per sec, amounted to 52.2 cu ft per sec per sq mile, on the 3 000 sq miles of drainage area between Moosehead and Waterville.



Station	Drainage Area in Sq Mi	Flow from Records of	Peak Flow	
			Cu Ft per Sec	Cu Ft per Sec per Sq Mi
Moosehead Outlet	1 240	Gaging Sta.	1 470*	1.2*
The Forks	1 570	Gaging Sta.	15 800	10.0
Bingham (Wyman Dam)	2 700	Power Plant	54 000	20.0
Skowhegan	3 850	Power Plant	133 500	34.7
Waterville	4 270	Power Plant	157 000	36.8

* Completely Regulated by Storage

FIG. 7.—KENNEBEC RIVER HYDROGRAPHS, FLOOD OF MARCH, 1936

These hydrographs of the flood on the Kennebec River show graphically the great value of the storage of the Moosehead System. In the period, March 12 to 26, inclusive, 16 300 000 000 cu ft (375 000 acre-ft) was stored in Moosehead, a raised natural lake, and Brassua, an artificial reservoir, and practically no flow was released. The quantity stored is equivalent to 5.7 in. over the Moosehead water-shed of 1 240 sq miles, or 1.7 in (about 23% of the run-off) over the entire drainage area above Waterville. Another measure of the value of this storage is shown by a comparison of the run-off of the Dead River and Moosehead Lake. The Dead River, an important tributary immediately below Moosehead Lake, with no storage and with a drainage area much like that of Moosehead, had a peak run-off of 32.4 cu ft per sec per sq mile, and a total run-off of 8.5 in. from a drainage area of 878 sq miles. On the other hand, there was practically no flow from the Moosehead drainage area, all the run-off going into storage.

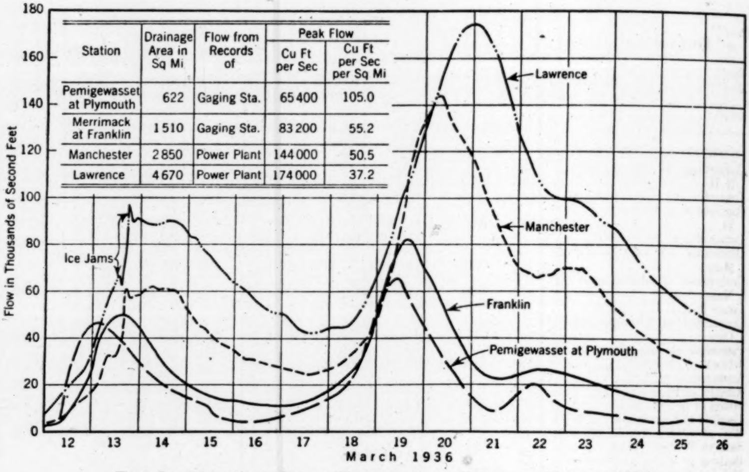
Merrimac River.—The flow of the Merrimac River is shown in Fig. 8, together with the flow of the Pemigewasset River, at Plymouth, N. H. At Lawrence, Mass., the shape of the first peak on March 13 and 14 is considerably distorted. An ice jam was formed at a bend in the Merrimac River about a mile above Lawrence in the early evening of March 13, and caused first a drop and then a very rapid rise of the water level.

For the period, March 12 to 26, inclusive, the run-off at Lawrence was equivalent to 9.6 in. over the entire water-shed, which is 49% of the mean annual run-off based on 55 yr of record. At Franklin, N. H., the flood run-off was 9.8 in., indicating that the run-off was uniformly distributed over the entire water-shed. This fact is also indicated by the high run-off of tributaries all over the water-shed (see Table 3).



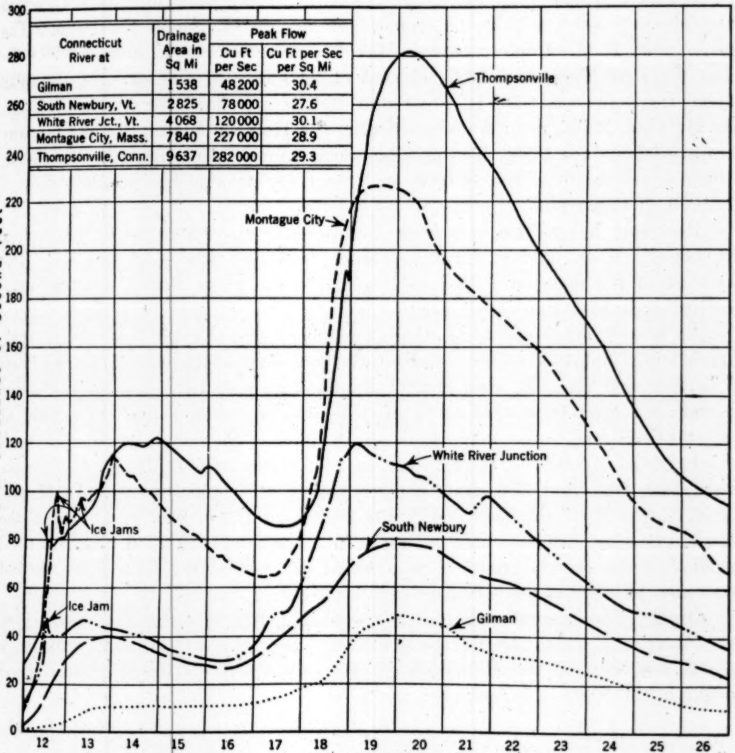
Station	Drainage Area in Sq Mi	Flow from Records of	Peak Flow	
			Cu Ft per Sec	Cu Ft per Sec per Sq Mi
Pemigewasset at Plymouth	622	Gaging Sta.	65 400	105.0
Merrimack at Franklin	1 510	Gaging Sta.	83 200	55.2
Manchester	2 850	Power Plant	144 000	50.5
Lawrence	4 670	Power Plant	174 000	37.2

Fig. 8.—Merrimac River Hydrographs, Flood of March, 1936.

The magnitude of the flood peaks on the main river was considerably reduced by valley storage. Between the Lawrence Dam and the junction of the Winnepesaukee and Pemigewasset Rivers, at Franklin, the valley storage amounted to about 17 500 000 000 cu ft (400 000 acre-ft) equivalent to 1.6 in. over the water-shed above Lawrence. The total amount of reservoir storage now developed above Lawrence is 12 000 000 000 cu ft (276 000 acre-ft).

Connecticut River.—The flow of the Connecticut River at five U. S. Geological Survey Stations is shown in Fig 9. Two floods occurred on this river, one having its peak on March 13 and 14, and the other on March 19 and 20. The first peak was confined largely to the middle and lower parts of the water-shed, as indicated by the fact that it amounted to only 11 000 cu ft per sec, or 7.2 cu ft per sec per sq mile, at Gilman, Vt., as compared with 14.7 cu ft per sec per sq mile at Montague City, Mass. This first peak was not as high relatively as the corresponding peak on the Merrimac River. At Montague City the peak of March 13, which reflects some interference by ice jams, was about 115 000 cu ft per sec, and the average daily flow was 110 000 cu ft per sec, or 14 cu ft per sec per sq mile. In the 56 yr of record on the Lower Connecticut River, flows of this magnitude have occurred only in 1895, 1896, and 1927.

On the Connecticut River, the valley storage was relatively greater than on the Merrimac River. Between the Thompsonville Dam (Windsor Locks, Conn.), and Waterford, Vt., the total valley storage was approximately 42 400 000 000 cu ft (974 000 acre-ft), equivalent to 1.9 in. on the water-shed above Thompsonville. The total quantity of water stored in existing power storage reservoirs in the period, March 12 to 26, inclusive, was about 8 000 000 000 cu ft (184 000 acre-ft) equivalent to about 0.4 in. on the water-shed above Thompsonville.



Connecticut River at	Drainage Area in Sq Mi	Peak Flow	
		Cu Ft per Sec	Cu Ft per Sec per Sq Mi
Gilman	1 538	48 200	30.4
South Newbury, Vt.	2 825	78 000	27.6
White River Jct., Vt.	4 068	120 000	30.1
Montague City, Mass.	7 840	227 000	28.9
Thompsonville, Conn.	9 637	282 000	29.3

FIG. 9.—CONNECTICUT RIVER HYDROGRAPHS, FLOODS OF 1936.

The second peak prevailed over the entire water-shed, the unit run-off being between 27 and 30 cu ft per sec per sq mile for all the stations. For the entire period the run-off at all the stations, except Gilman, was about 8.5 in., and that at Gilman was 7.7 in. This is about 40% of the mean annual run-off (30 yr of record) of 22 in.

LONG-TERM RECORDS

More long-term records are available in New England than in other regions of the United States. The magnitude of the 1936 flood can be best judged by a review of these records on various streams. Reference is made in this connection to Table 3. The following detailed remarks are also of interest.

Connecticut River.—At Hartford, Conn., a record of river stage has been kept since about 1836. Scattered observations of great flows go back to 1683. On March 20, 1801, there was a great flood, with a river stage of 27.5 ft. From contemporary newspaper accounts, it appears that this exceeded any previous stage within the memory of any one living at that time. The next great flood, which occurred May 1, 1854, reached a stage of 29.8 ft. The flood of November, 1927, crested at 29.0 ft. At the peak of the 1936 flood, the stage was 37.3 ft, greatly exceeding any flood for at least 150 yr. At Holyoke, Mass., records maintained by the Holyoke Water Power Company are available since 1880. The previous maximum flood occurred in November, 1927, when the flow was 169 000 cu ft per sec as against the 1936 flow of 222 000 cu ft per sec.

Merrimac River.—Records have been kept by the water power companies, at Lowell, Mass., and at Lawrence since 1846 and 1848, respectively. The average of the maximum flood each year for the 91-yr record, 1846 to 1936, inclusive, is 46 600 cu ft per sec.

At Lowell, in that period, there have been five great floods: 1852, 1895, 1896, 1927, and 1936. The notes of the late James Bicheno Francis, Past-President and Hon. M. Am. Soc. C. E., the Engineer in charge of the water power at Lowell from 1845 to 1885, state that, in 1785, there was a flood of substantially the same magnitude as in 1852. The latter reached a peak discharge of 108 000 cu ft per sec. In 1895, 1896, and 1927, the flood peaks were 18.9, 20.8, and 17.3 cu ft per sec per sq mile, respectively. In March, 1936, the peak of the "ice flood" was 90 000 cu ft per sec, and that of the week following, 173 000 cu ft per sec. In other words, in 1936, the first flood peak was the fourth greatest in a period of about 200 yr, and the second exceeded by 65% any flood on record.

On the Pemigewasset River (drainage area, 622 sq miles), a tributary of the Merrimac which drains the southern slope of the White Mountains, a record has been kept at Plymouth, N. H., since 1886. The five greatest flood peaks in the 50 yr of record are:

Date	Cubic Feet per Second	Cubic Feet per Second per Square Mile
July 15, 1897	32 800*	52.7
April 29, 1923	33 800	54.3
November 4, 1927	60 000	96.4
March 13, 1936	46 200	74.3
March 19, 1936	65 200	105.0

Kennebec River.—At Waterville the approximate height of the great floods since about 1836 has been obtained on a landmark known as the "freshet oak". Elevations of the scars left by the great freshets are as follows:

Date	Elevation, in Feet	Date	Elevation, in Feet
May 22, 1832	104.8	April 30, 1887	102.2
October, 1854	102.8	December 16, 1901	105.14
October, 1869	102.7	March 20, 1936	106.3

---

* Average daily flow. No data available on the flood peak, which presumably was higher.

The flood of May 22, 1832, had an estimated peak of 140 000 cu ft per sec.[10] The flood of December 16, 1901, had a peak flow of 157 000 cu ft per sec, as measured at the Hollingsworth and Whitney Dam about a mile up stream. The flood of March, 1936, also had a peak flow of 157 000 cu ft per sec, as measured at the Hollingsworth and Whitney Dam. Because of the heavy run of ice, the scar left by this freshet was very wide. The elevation given is of the middle of the scar and may not be an accurate record of the maximum flood stage.

Comparison of the 1936 and the 1927 Floods

In spite of the fact that the 1936 flood was greater than any on record on most of the large rivers in New England, the flows per square mile on some of the medium and small water-sheds were greater in the 1927 flood (see Table 3 and Fig. 3).

For drainage areas of about 1 000 sq miles, the maximum flow on record is that of the Winooski River at Essex Junction, Vt., 111 cu ft per sec per sq mile. In 1936, no flow of more than 60 cu ft per sec per sq mile was measured on a drainage area of this size.

For drainage areas of about 500 sq miles, the 1927 unit flows were also much greater. In 1927, the White River (Vermont) had a peak of 174 cu ft per sec per sq mile on a drainage area of 690 sq miles. In the 1936 flood the nearest approach to this unit flow occurred on the Pemigewasset River, at Plymouth (104.8 cu ft per sec per sq mile for a drainage area of 622 sq miles).

As for areas of less than 100 sq miles, in 1927, unit flows of 303 and 257 cu ft per sec per sq mile occurred on drainage areas of 38 and 67 sq miles, respectively—Jail Branch and North Branch, tributaries of the Winooski River. (Detention basins on these two streams were completed in 1935 by the Army Engineers.) No flows of this magnitude were recorded in 1936, the greatest comparable unit flows being 201 and 169 cu ft per sec per sq mile, on two areas of about 30 sq miles each, tributary to the Souhegan River in the central part of the Merrimac water-shed.

Flood Damages

The amount of damage caused by the 1936 flood has been investigated by a number of public agencies, including the Massachusetts State Planning Board, the New Hampshire Flood Reconstruction Council, and the Providence, R. I., and Boston, Mass., District Offices of the Corps of Engineers, U. S. Army. The work of gathering and tabulating these data is largely completed (1937) although some of the figures given are subject to some further correction. These figures do not include estimates of indirect or consequent damages, such as loss of business.

The total flood damage in New England amounted to about $70 000 000, of which $67 893 000 is included in the nine river basins listed in Table 4, and comprises the areas where the damage was heavy. The areas not included

---

[10] H. R. Doc. No. 658, 71st Cong., 3d Sess.

(the St. John and St. Croix River basins in Northern Maine, and the western slope of Vermont, tributary to Lake Champlain) were not badly damaged.

TABLE 4.—ESTIMATE OF DAMAGE CAUSED BY THE NEW ENGLAND FLOODS OF MARCH, 1936

River basin	Drainage area, in square miles	Damages	
		Total	Per square mile
Penobscot	8 570	$369 000	$430
Kennebec	5 970	1 494 000	250
Androscoggin	3 470	3 574 000	1 030
Saco	1 720	1 401 000	810
Merrimac	5 015	20 148 000	4 010
Blackstone	540	1 879 000	3 470
Thames	1 470	3 633 000	2 470
Connecticut	11 320	34 500 000	3 050
Housatonic	1 930	895 000	460
Total	40 005	67 893 000	.....
Average	......	....	$1 700

In its report of April 25, 1936, the New Hampshire Flood Reconstruction Council estimated the total flood damage in that State at $10 417 924. It was divided as follows:

Highways and bridges		$4 257 214
Other public property (including municipal utilities)	$229 855	
Quasi-public property	39 345	
		269 200
Utilities and railroads	$1 983 813	
Less municipal utilities	49 855	
		1 935 958
Industries: Manufacturing, wholesale, and retail establishments		2 868 857
Recreational facilities		10 000
Farms and rural property		426 695
Other private property		650 000
Total		$10 417 924

The population of New Hampshire in 1930 was 465 293, and the taxable wealth in 1922 was $1 283 000 000. The estimated damage amounted to $21.90 per capita, or 0.81% of the taxable wealth.

The Massachusetts State Planning Board has made an estimate of the total damage in Massachusetts. At the present time (March, 1937) this estimate is about complete, and accounts for damages of $35 773 926, made up as follows:

Highways	$2 943 760
Highway bridges	5 085 343
Water supply and sewerage systems	571 030

Other municipal losses	$754 871
Railroads	1 305 631
Other utilities	1 638 555
Industrial and commercial	16 872 255
Dams	714 650
Residential	5 070 078
Crop lands	817 753
Total	$35 773 926

The population of Massachusetts, in 1930, was 4 249 614, and the taxable wealth, $22 552 000 000. The estimated damage amounted to $6.25 per capita, or 0.115% of the total taxable wealth.

For some of the tributaries estimates of damage are virtually complete. Two are given herein, one of the damage on the Millers River water-shed, the other on the Pemigewasset River water-shed.

The Millers River lies on the eastern slope of the Connecticut River, which it enters a short distance above Greenfield, Mass. The drainage area is 393 sq miles, and the total fall of the main river is about 800 ft in 37 miles. There are eight large towns along the river. Some of the rural land is farmed, but a large proportion is woodland. The towns and industries are centered around the many low-head water-power developments.

There were two flood peaks on the Millers River, the first being accompanied by ice jams which caused much damage. The second peak was considerably higher than the first one, and attained a unit discharge of 53.2 cu ft per sec per sq mile on a drainage area of 370 sq miles at Erving, Mass. This is about three times as great as any other peak observed in the 22-yr record. The damages were estimated, as follows:

Highways	$189 531
Highway bridges	471 200
Water supply and sewerage systems	34 980
Other municipal losses	0
Railroads	226 800
Other utilities	95 000
Industrial and commercial	925 450
Dams	158 500
Residential	241 825
Crop lands	9 060
Total	$2 352 346

The total population of the Millers River water-shed is about 50 000, making the per capita damage about $47.

The Pemigewasset River has a total drainage area of 1 085 sq miles on the southern slope of the White Mountains. The water-shed is largely wooded and is sparsely settled. Most of the permanent population is concentrated in a few towns in the lower valley. There is a large summer population, particularly on Squam and Newfound Lakes and in the vicinity of Franconia Notch. The 1936 flood flows are shown on Fig. 9. The damages were estimated as follows:

Commercial	$57 000
Industrial	225 000
Residential	156 000
Municipal	12 000
Utilities	25 000
Railroads	180 000
Highways	112 000
Highway bridges	30 000
Farms	232 000
Total	$1 029 000

Effect of Ice Jams.—A large part of the total flood damage in 1936, particularly in Maine, was caused by the ice that went out with the peak of March 13. Ordinarily, the spring freshets come after a period of warm weather that to some extent melts and rots the ice sheet in the mill ponds. In 1936, however, the freshet came very early, and the ice went out as hard, "blue" ice. As a result, ice jams accompanied the progress of the flood peak down river.

On the Androscoggin and Kennebec Rivers, the ice jams were particularly spectacular and destructive. On March 20, an ice jam dammed the river at the head of the mill pond of the Gulf Island Hydro-Electric Station. This jam was about ½ mile wide and 1¼ miles long, and extended 20 ft above the water level. When it broke, it created a rise of 1.2 ft in the pond level, equivalent to about 500 000 000 cu ft (11 500 acre-ft), in less than 30 min. An 80-ft highway truss rode the ice jam, and finally passed through one of the Tainter gates on the dam, buckling on the spillway crest as it went through.

On the Kennebec River the greatest damage was due to an ice jam in the tidal part of the river. This jam took out the piers of a modern highway bridge, valued at $260 000 and carried the spans some distance down stream, on top of the ice, in a part of the river where the depth was about 50 ft.

On the Connecticut River, an ice jam at the head of the mill pond above Holyoke, Mass., blocked the river so that it finally cut a new channel to the east of the old one.

ECONOMICS OF FLOOD CONTROL

In a period of 200 yr, no other floods in New England have caused damage approaching that of the floods of 1927 and 1936. The question of how much this region is justified in spending on preventive measures presents itself.

In a study of the economics of flood control there are two distinct problems. The first concerns the design and construction of individual river structures that affect the natural flow and the occupancy of the natural floodplains, and the second concerns the construction of works which will prevent or reduce flood flows on the entire river or in certain localities.

The first problem must be solved by the individual owners of properties of various kinds—dams and power plants, bridges, industrial buildings, river walls, railroad and other embankments, and, of course, homes. Damage to river structures during floods indicates that many of them were constructed without adequate engineering design and supervision.

It is difficult to determine how far it is profitable to go in the design of a structure to prevent possible flood damage where property damage alone is involved. Where life is endangered there can be only one answer, but the temporary loss of the use of property or even its partial destruction once in 25, 50, or 100 yr, may not warrant design and construction to prevent all damage.

Attempts have been made to rationalize the second problem, namely, that of flood prevention or reduction, on a purely economic basis. If definite information were available, the solution would be relatively simple; the maximum expenditure economically justified to prevent recurrence of certain flood damages would be the capitalized present worth of the damages over the period of flood frequency causing them.

Because of the lack of definite scientific data on floods which occurred before about 1850, however, it is difficult to establish an accurate basis for computing the frequency of floods of certain magnitudes. This does not mean that no attempt should be made to make economic studies; it does indicate that all possible information should be collected and studied, impartially analyzed, and tested by all known methods.

Estimating the damages due to the 1927 flood on the Winooski River, in Vermont, to have been $13 500 000, the flood frequency, 100 yr, and giving consideration to other floods, the U. S. Army Engineers estimated[11] that the expenditure warranted to provide adequate control of this stream would be $433 000, based on a 3½% interest rate.

It is further stated that the Winooski Valley can be adequately protected from flood damage by a series of detention reservoirs designed solely for flood control, but that the cost "is far beyond the amount which can be economically justified."

This conclusion is the one generally arrived at from a study of flood protection on the larger New England streams. For a specific case on a small stream where the damage may run very high, or where the opportunities for flood control are unusually favorable, it may be that flood-control measures can be economically justified.

PREVENTION OF FLOOD DAMAGES

Most of the practical means of reducing flood damages have to do with such matters as flood warnings, storage reservoirs, detention basins, river channel improvements, or river structures, such as dams, bridges, and levees. Of these items, flood warnings and storage reservoirs are of greatest general interest in New England, since they are the most practical measures. Storage reservoirs may provide flood protection for large areas, although not primarily developed for that purpose.

---

[11] H. R. Doc. 785, 71st Cong., 3d Sess.

Since the 1927 flood a few detention basins have been built in New England to protect a comparatively small area. Technically, they are perfectly satisfactory, and will serve their purpose if they are maintained properly, but their cost under New England conditions will be found to be prohibitive except in rare instances. The other items mentioned are principally of local interest, but of great importance, and are receiving consideration in many places.

Flood Warnings.—The U. S. Weather Bureau is the formal agency in New England which maintains flood stations that report to it and from which flood warnings are issued if the occasion arises. It is proper to question the adequacy of this service and to make suggestions which may improve it.

The problem may be somewhat different in New England than elsewhere. The distances are relatively short except on the major streams, and on all these streams there are agencies which have a vital interest in the progress of floods, and, therefore, make it their business to keep informed. In some instances, this agency is an utility operating hydro-electric plants over a considerable part of the river. In other instances, as at Lewiston, Me., and Lowell, Mass., the company owning a water power also has an interest in up-stream storage and, for many years, has maintained a private system of communication to keep informed about threatened rises. Under existing conditions such information is of little value to the general public, since it is not given out except as an inquiring reporter may obtain it for his newspaper. Information concerning two important factors affecting floods is not generally available, namely, the extent and water equivalent of the snow cover and the condition of the ground beneath the snow. Numerous observations of precipitation in the form of snow are made by the Weather Bureau and other agencies. Public utilities owning water-power plants, and the winter sports organizations, take scattered observations on the amount of snow cover, but few measurements are made of its water equivalent.

Estimates by trained observers of the amount of snow cover and its water equivalent, at representative points in important areas, are needed. The District Engineers of the U. S. Geological Survey, whose assistants periodically visit the gaging stations in their charge to change charts, would seem to be in an excellent position to take this work on with little additional expense.

This agency also obtains considerable advance information about other conditions conducive to floods, from the reports of its field crews, who make periodic measurements and inspections on all the important streams and many of the tributaries. Again, this information is not made public except on request.

In some years snow falls before the ground freezes and never completely leaves the ground before the spring flood. Such a condition (more likely to be found in Northern New England), is one of the many factors that sometimes combine to cause the extreme run-off, and, consequently, should be a part of the data available to the forecasting agency.

One of two corrective steps is needed. Either a central forecasting agency should be set up to supplement the work of the Weather Bureau, or that body itself should take on additional duties and correlate all the information collected by private and public agencies, so that it may be made available to the public.

Newspapers and radio commentators invariably exaggerate threatened flood conditions, and the public, unable to judge between facts and exaggeration, usually discounts all such information because of its general unreliability. Regulations providing that none but official information be published or broadcast during a flood crisis might be helpful.

Sometimes, of course, meteorological conditions change so rapidly over small areas, that the event happens before the forecast can possibly reach the affected area. This was the case before the 1927 flood in Vermont.

Storage Reservoirs.—Economically, the most promising method of alleviating flood conditions on New England streams is the construction of storage reservoirs in which the reduction of flood peaks is incidental to their operation for increasing the low-water flow.

Storage reservoirs in New England are normally well down by October, and usually nearly empty by the end of winter, the periods when floods are most likely to happen. The larger reservoirs are not full much more than two months in an average year, and with competent management considerable water can be stored temporarily even on a full reservoir. Any temporary storage reduces the peak flow down stream.

In its report, the Committee on Floods of the Boston Society of Civil Engineers states[12]: "The most desirable policy toward the flood problem here in New England appears to be to encourage in every way the construction of reservoirs for power purposes."

The Advisory Committee of Engineers on Flood Control in the State of Vermont, in a report after the 1927 flood. made substantially the same recommendation, as did the Army Engineers in their reports on flood control on many of the New England rivers.

Effectiveness of Storage Reservoirs for Flood Control.—As a test of the effectiveness of storage reservoirs for flood control, an examination has been made of several existing storage reservoirs to see how much capacity was available at the beginning of various floods of record.

Lake Winnepesaukee (Merrimac Water-Shed).—In Lake Winnepesaukee, 7 000 000 000 cu ft (161 000 acre-ft) of storage is made available by works built about 1845 which permit the lake level to be drawn down 40 in. Restrictions occasioned by the use of the lake in the summer for recreational purposes require that if the gage registers 21 in., or less, the outflow is limited to a daily average of 250 cu ft per sec. Floods begin to cause damage in the Merrimac Valley when the average daily flow at Lawrence reaches about 60 000 cu ft per sec. In the period from 1870 to 1935 there were eight floods of this magnitude, or greater. Table 5 shows the percentage of full reservoir capacity available at the beginning of each. The behavior of Lake Winnepesaukee in the 1936 flood is discussed later in detail.

Moosehead Lake (Kennebec Water-Shed).—Damage due to floods in the Lower Kennebec Valley starts with an average daily flow of about 87 000

---

cu ft per sec, at Waterville, Me. In the period, 1895 to 1926, five freshets of this magnitude or greater have occurred. In four of these floods, the quantity of water stored in Moosehead Lake was an important factor in reducing flood peaks in the Lower Kennebec River (see Table 6).

* Capacity, 20 600 000 000 cu. ft. (473 000 acre-ft.).

After 1926 additional storage was created on the Moosehead Lake drainage area by the construction of Brassua Reservoir, with a capacity of 8 600 000 000 cu ft (197 000 acre-ft). The contributing area is 675 sq miles. On March 12, 1936, only 945 000 000 cu ft (21 700 acre-ft) (5% of its total capacity) was stored in Moosehead Lake, and Brassua Lake was empty. Therefore, at the start of the 1936 flood, practically the entire capacity of the two reservoirs was available for the storage of flood flows.

Effectiveness of Power Storage Reservoirs in Reducing 1936 Flood Peaks.—An examination has been made of the amount by which storage reservoirs reduced flood peaks in the 1936 flood, on several streams where sufficient data were available.

Lake Winnepesaukee (Merrimac Water-Shed).—On March 10, 1936, Lake Winnepesaukee was 22% full. In the period, March 10 to 26, inclusive, the total yield of the Lake Winnepesaukee drainage area was 8 860 000 000 cu ft (203 000 acre-ft) (the equivalent of 10.6 in. of run-off). Of this quantity, 7 500 000 000 cu ft (172 000 acre-ft) was stored in the lake, only a few hundred second-feet being released until March 21, two days after the peak had passed Franklin, N. H.

On Fig. 10 is shown the effect of this storage on the average daily discharge of the Merrimac at Franklin, the point where that stream is formed by the junction of the Winnepesaukee River (drainage area, 480 sq miles) and the Pemigewasset River (drainage area, 1 010 sq miles).

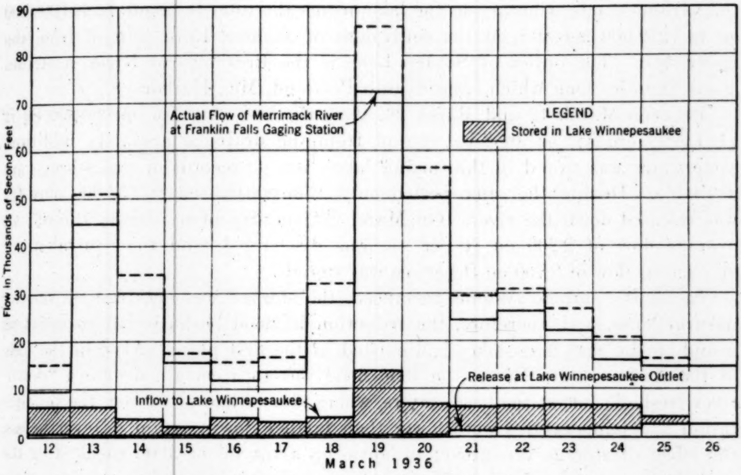

Fig. 10.—Effect of Lake Winnepesaukee Storage, Flood of March, 1936

It seems reasonable to assume that the momentary peak at Franklin, which occurred about 2:00 P. M., on March 19, and amounted to 83 000 cu ft per sec, was reduced by about 9 000 cu ft per sec. The corresponding reduction in gage height is about 3 ft.

At the dams below, the reduction was somewhat less, because of the greater time of transit and the effect of channel storage. It is estimated that at the Sewall Dam and the Garvins Falls Dam, 16 and 28 miles, respectively, below Franklin, the reduction in flow due to Winnepesaukee storage was about 8 000 cu ft per sec, equivalent to a reduction of about 0.75 ft of the flood peak.

Rangeley System (Androscoggin Water-Shed).—During the 1936 flood, 13 000 000 000 cu ft (299 000 acre-ft) was stored in the Rangeley Reservoir System in the period between March 12 and March 26. Releases during the same period totaled only about 420 000 000 cu ft (9 600 acre-ft), and did not begin until March 22, when the flood peaks had passed Rumford, Me. The total quantity stored was equivalent to 5.1 in. of run-off over the water-shed, or to an average flow of 10 000 cu ft per sec for the period.

Because of the number of units comprising the system, it is difficult to estimate the effect of this storage on the flood peaks. However, on the rigorous assumption that the reduction in peak flow was no greater than the reduction in the average flow for the period, it amounted to about 13.5% at Rumford, 84 miles below the lowest reservoir. The corresponding reduction in height over this dam was about 1.5 ft.

Sebago Lake (Presumpscot River).—As an example of complete storage, the behavior of Sebago Lake is interesting. Sebago Lake, a natural lake with an area of 45.6 sq miles, was raised about 8 ft by means of a dam at the outlet, built in 1878. The storage available is about 9 700 000 000 cu ft (223 000 acre-ft) on a drainage area of 360 sq miles. Additional storage in the various ponds tributary to the lake brings the total to about 12 600 000 000 cu ft (289 000 acre-ft), or the equivalent of about a 15-in. run-off from the water-shed. The outlet of Sebago Lake is the Presumpscot River, a stream about 22 miles long which empties into Portland, Me., Harbor.

Between March 12 and March 26, 1936, the lake stored 6 700 000 000 cu ft (154 000 acre-ft), or an 8-in. run-off from the drainage area. In addition, some water was stored in the smaller lakes, but no records of this storage are available. During the same period only 2 300 000 000 cu ft (53 000 acre-ft) was released down the river. On March 22, the day of maximum run-off, an average flow of 2 200 cu ft per sec was discharged, and the equivalent of an average flow of 8 700 cu ft per sec was stored.

In all the storage systems instanced, the storage was obtained by raising natural lakes, and, therefore, the reduction in flood peaks is not so great as would be the case if no lakes had existed in the first place. Also, in the case of the Androscoggin River, the 1936 flood was to a certain degree a "down-river freshet", for, at the head-waters, where the storage is located, the precipitation and temperatures were lower than farther down stream. Nevertheless, the effect of storage was great; to bottle up a run-off of 5 in. until after the peak is past, is of great benefit.

Deerfield River Storage.—The effects of storage were analyzed on one stream, the Deerfield River, where there are no natural lakes. The Deerfield is an important tributary of the Connecticut River, rising in the Green Mountains in Southern Vermont, and flowing south and east to join the Connecticut just below Turners Falls, Mass. The water-shed is mountainous, with steep rocky slopes, and the stream is characterized by flashy floods and high run-off. Two reservoirs, Somerset and Harriman (formerly known as Davis Bridge), with drainage areas of 30 and 184 sq miles, respectively, have been built by the New England Power Company, the former in 1913, the latter in 1924. Somerset Reservoir completely controls the 30 sq miles above it, the storage capacity amounting to 38.9 in. on the water-shed. The Harriman Reservoir largely controls the 154 sq miles below Somerset, the storage amounting to 14.1 in. on the water-shed.

In the 1936 flood, no water was wasted from Somerset Reservoir. At Harriman Reservoir, except for a few hundred second-feet used for power purposes, no water was released until March 27, a week after the crest of the Connecticut River flood. It is estimated that these two reservoirs reduced the flood peak at Shelburne Falls, Mass., where the drainage area is about 500 sq miles, from 72 000 to 48 000 cu ft per sec, with a corresponding reduction of gage height of 3.3 ft.

Table 7 illustrates further the value of storage reservoirs in time of flood, giving the quantity of water stored and the storage capacity remaining after the 1927 and 1936 floods.

Studies of Potential Developments.—At present (1937) many different plans of flood control by means of storage reservoirs are being developed by various State and Federal agencies. The scope of this paper does not permit a detailed analysis of the effect of any of these projects on flood peaks. Such analyses have been made, however, in several cases, and a few of the conclusions are quoted.

TABLE 7.—BEHAVIOR OF NEW ENGLAND STORAGE RESERVOIRS—FLOODS OF NOVEMBER, 1927, AND MARCH, 1936

* Effective. † Combined. ‡ Data not available.

The New Hampshire Water Resources Board has proposed four storage reservoirs on the water-shed of the Merrimac River, to be built primarily to increase the low-water flow of the river and, secondarily, to reduce floods. These reservoirs would have a total capacity of about 18 000 000 000 cu ft (414 000 acre-ft) and a contributing drainage area of 600 sq miles. In a report on the March, 1936, flood[13], Richard S. Holmgren, M. Am. Soc. C. E., Chief Engineer of the New Hampshire Water Resources Board, estimates that the proposed system of reservoirs would have reduced the 1936 peak flow at Manchester, N. H. (drainage area, 2 854 sq miles), from 114 000 to 85 000 cu ft per sec, with a reduction in the height of water at the Amoskeag Dam, at Manchester, N. H., of 3.1 ft. At the Lowell (Mass.) Dam, he estimates that the flow would have been reduced from 173 000 to 145 000 cu ft per sec, with a corresponding reduction in gage height of 3.0 ft.

In 1935–1936, the Army Engineers made a comprehensive report[14] on the Connecticut River on "the efficient development of its water power, the control of floods, and the needs of navigation." In this report they recommend an "initial flood control plan", which would include ten proposed reservoirs operated primarily for the control of floods and, secondarily, for the generation of power. The reservoirs would have a combined contributing drainage area of 951 sq miles, a capacity below the spillway level of 11 700 000 000 cu ft (269 000 acre-ft), and a capacity above the spillway level of 3 670 000 000 cu ft (84 000 acre-ft). The report states (page 85),

---

[13] "Extent and Magnitude of the March, 1936, Flood in New Hampshire."

[14] H. R. Doc. 412, 74th Cong., 2d Sess.

> "If the reservoirs of the initial program had been in operation during the 1927 flood, they would have been depleted at the time of the flood under normal operating conditions by 50% of their capacity. * * * Six of the reservoirs would have given almost complete protection at the dam site. * * * On the main stream, the peak at White River Junction would have been reduced by approximately 46% from 148 000 second-feet to about 80 000 second-feet."

Detention Reservoirs.—In Vermont, as a result of comprehensive investigations following the 1927 flood, two detention reservoirs were built on tributaries of the Winooski River and put into operation in 1935. The dams were designed by members of the Corps of Engineers, U. S. Army, and built under their supervision.

As originally planned[15], these reservoirs were large enough for power storage as well as flood control As finally built, however, the dams were lower and their operation was restricted to flood control, with uncontrolled outlets of such size that with the reservoirs full the discharge would still remain within the banks of the stream below. Both dams have wide crests, so that their height may easily be increased if it should prove desirable in the future to provide storage for power purposes.

The Wrightsville Dam is on the North Branch of the Winooski River and controls a drainage area of 71 sq miles. The reservoir has a capacity of 895 000 000 cu ft (20 500 acre-ft) to the spillway crest and 1 000 000 000 cu ft (23 000 acre-ft) to the maximum flow line, equivalent to 5.4 and 6.1 in., respectively, on the water-shed.

The East Barre Dam is on the Jail Branch of the Winooski River and controls a drainage area of 39 sq miles. The reservoir has a capacity of 523 000 000 cu ft (12 000 acre-ft) to the spillway crest and 706 000 000 cu ft (16 200 acre-ft) to the maximum flow line, equivalent to 5.3 and 7.8 in., respectively, on the water-shed.

It should be noted that these reservoirs are in the area in which some of the highest unit flows were recorded in the 1927 flood, that at Wrightsville being 257 cu ft per sec per sq mile and that at East Barre, 303 cu ft per sec per sq mile.

In the 1936 flood, the unit flows were not so high on the Vermont streams; nevertheless, the run-off was high enough to constitute a real test of the effectiveness of these detention reservoirs. At Wrightsville, the maximum rate of inflow, computed from the rise in the reservoir, was 3 960 cu ft per sec (55.8 cu ft per sec per sq mile), and the rate of discharge through the outlet at this time was 870 cu ft per sec (12.3 cu ft per sec per sq mile), a reduction in the flood peak of 78 per cent. The maximum rate of outflow was 960 cu ft per sec. The maximum quantity stored was equivalent to 4.2 in. on the drainage area, or 78% of the total capacity of the reservoir. At East Barre, the maximum rate of inflow was 2 035 cu ft per sec (52.2 cu ft per sec per sq mile), and the concurrent rate of discharge was 427 cu ft per sec (10.9 cu ft per sec per sq mile), a reduction in flood peak of 79 per cent. The greatest rate of outflow was 450 cu ft per sec. The maximum quantity stored was 5.6 in. on the water-shed, or about 95% of the capacity to the spillway level.

---

[15] H. R. Doc. 785, 71st Cong., 3d Sess.

It is estimated by the Army Engineers that these two detention reservoirs, regulating 110 sq miles, reduced the peak flow of the Winooski River, at Montpelier, Vt., where the drainage area is 418 sq miles, from 23 700 to 19 200 cu ft per sec.

A computation has been made of the potential effect of the Wrightsville Dam on flows similar to those in 1927. A hydrograph was used based in general on the "standard 100-yr flood",[16] with a total run-off of 5.2 in. in 27 hr and a peak flow of about 250 cu ft per sec per sq mile. With the reservoir in operation the peak flow would have been reduced from 17 000 to about 800 cu ft per sec. The maximum storage would have been 89% of the reservoir capacity.

CONCLUSIONS

Comparatively little definite information is available about floods, the conditions under which they have occurred, and the inconvenience, loss of life, and economic losses they have caused.

Predictions relative to 1 000-yr and even 100-yr floods are based on meager information. Except for a few records covering less than 100 yr, the basic data are largely legendary. The importance of collecting additional data should be stressed.

The determination of future flood flows at a specific point on any river should include a study of the flood records of all streams having similar physical and climatological aspects.

Existing storage reservoirs have appreciably reduced the flood flows on several streams. Additional reservoir sites, many of which can undoubtedly be economically developed, are available on the head-waters of most of the New England rivers and their tributaries.

In some cases, it will be necessary to provide for joint action by all the water users on a river in order to develop the storage economically. Such action can be furthered by legislation similar to that creating the New Hampshire Water Resources Board. This Board can initiate and carry out comprehensive developments under certain conditions. With regard to some of the larger streams, which pass through several States, it may be necessary to set up interstate compacts before some of the available storage sites can be developed economically.

Except for local improvements, which will undoubtedly be carried out regardless of economic considerations, the possibilities of strictly economic flood protection on New England rivers other than by storage reservoirs are believed to be scarce. Such possibilities are increased as the concept of the economics of flood protection is broadened by considerations of public policy.

---

[16] H. R. Doc. 708, 71st Cong., 3d Sess., Figs. 9 and 10.

Flood-protection works on the upper reaches of the large rivers, and on their tributaries, will have only a very minor effect on the lower reaches, where much of the damage during extreme floods occurs.

Considering the many combinations of conditions which may cause flood flows on the lower reaches of the larger rivers, calculations of stage reductions due to hypothetical reservoirs, or other practical works, on their upper reaches are somewhat academic since they must be based on meager flood-flow information. It seems sufficient to state that any reduction whatever is desirable, but that the extent of such reduction will vary with conditions.

ACKNOWLEDGMENTS

This paper could not have been written so soon after the 1936 flood without the co-operation of the public and private agencies that have been collecting data and have made available data which were still being analyzed. Particular mention should be made of the following agencies and individuals: The Boston, Mass., Office of the U. S. Weather Bureau; the District Engineers of the Corps of Engineers, U. S. Army, in Boston, and in Providence, R. I.; the District Engineers of the U. S. Geological Survey in Boston, Augusta, Me., and Hartford, Conn.; the New Hampshire Water Resources Board; the Massachusetts State Planning Board; and, the Engineers of the New England Power Company, New England Public Service Company, Union Water Power Company, and Kennebec Water Power Company. The writer is also indebted to his associate, Mr. Truman H. Safford, whose assistance in preparing this paper was invaluable.

THE NEW YORK FLOODS OF 1935 AND 1936

BY ARTHUR W. HARRINGTON,[17] M. AM. SOC. C. E., AND
HOLLISTER JOHNSON,[18] ASSOC. M. AM. SOC. C. E.

SYNOPSIS

Although records, relatively long for this region, indicated a favored location in respect to the occurrence of great storms, within nine months, New York State was visited by two major floods, one in July, 1935, and the other in March, 1936. The flood of July, 1935, was caused by a storm of the thunder-shower type of unusually large areal extent in the south-central part of the State. Many small streams had peak discharges of more than 2 000 cu ft per sec per sq mile. The damage, especially severe along the small streams, might well be called dynamic damage. The flood of March, 1936, was caused by moderate rains and melting snow which produced record-breaking discharges, both peak and total, on the larger streams, chiefly in the Hudson and Susquehanna River basins. Damage was caused principally by inundation along the larger streams. More and better hydrologic records are needed as part of the basic data for the design and operation of flood preventive and control projects and the solution of the problems of engineering economics involved.

GENERAL

It is difficult to speak in general terms of New York State, which, in many ways, is a region of contrasts. In topography, geology, climate, vegetative cover, precipitation, and run-off, this State offers wide variations. It is doubtful whether any other State east of the Rocky Mountains can show more divergent conditions.

In general, Western New York is flat, a rich agricultural region of low run-off in which the Genesee River is the principal stream. The central part of the State is deeply furrowed by glacial action, the most striking evidence of which is seen in the Finger Lakes. Many small streams of this part have cut deep gorges and are characterized by swift, turbulent flow. The principal rivers (Fig. 11) are the Susquehanna, which flows south through Pennsylvania and Maryland to Chesapeake Bay, and the Oswego, which drains the Finger Lakes and empties into Lake Ontario. Eastern New York has two more or less distinct mountain ranges, the Adirondacks and the Catskills. The highest peak in the State is Mount Marcy, in the Adirondacks, 5 433 ft above sea level. This part of the State is drained principally by the Hudson and Delaware Rivers and by numerous smaller streams flowing into the St. Lawrence River and Lake Champlain.

---

[17] Dist. Engr., U. S. Geological Survey, Albany, N. Y.

[18] Hydr. Engr., U. S. Geological Survey, Albany, N. Y.

With the possible exception of the Hudson, New York State has no large interior rivers, principally because it is so divided by major water-shed lines that the run-off goes in all directions. The Hudson, Delaware, and Susquehanna Rivers, all of which rise in New York, flow directly into the Atlantic Ocean. The Genesee, Oswego, and Black Rivers are tributary to Lake Ontario. The northern and northeastern parts of the State are in the St. Lawrence drainage basin, and a small area in the extreme western part is tributary to the Mississippi through the Allegheny and Ohio Rivers.

FIG. 11.—MAJOR DRAINAGE BASINS OF NEW YORK STATE

The Adirondack region is for the most part heavily forested, the Catskill region much less so. As of 1937, reforestation is being undertaken in a comprehensive manner by the New York State Department of Conservation in nearly all parts of the State, through the purchase and planting of marginal farm land. Unused farm lands are also being reforested to some extent by natural processes. What effect this gradual change in cover will have on stream flow is unknown at present. An investigation by the U. S. Geological Survey, in co-operation with the Division of Lands and Forests of the State Department of Conservation, is under way and eventually should yield valuable information on this subject.

It is well known that the areal distribution of precipitation in New York State is variable, but unfortunately only meager information is available for the areas of maximum precipitation, which are wild and inaccessible. The prevailing winds are westerly or southwesterly, and because the Adirondacks act as a barrier, the heaviest precipitation in the State occurs in certain areas on the western slopes of these mountains. Although substantiating records are not available, it seems probable that an annual precipitation of more than 75 in. occurs in some parts of this region.

Variations in run-off are noteworthy and can be illustrated by two examples of extremes. During the eight water-years from October, 1924, to September, 1932, the mean annual run-off from the 75 sq miles of drainage area above the gaging station on the East Branch of Fish Creek, near Constableville, was 48.5 in., whereas, during the same period, the run-off from 2 530 sq miles above the gaging station on the Chemung River, at Chemung, was only 13.4 in. All possible gradations of run-off occur between these extreme conditions.

HYDROLOGIC HISTORY PRIOR TO 1935

At present, the U. S. Weather Bureau maintains about 175 precipitation stations in New York State, co-operative and otherwise. Precipitation is recorded by other agencies at a few additional points. Relatively few of the continuous records extend back farther than about 1889, at which time the New York State Weather Service was created by Act of Legislature. Three of these continuous records, however, date from prior to 1830. The U. S. Geological Survey maintains at present 102 gaging stations in the State, but the average length of record per station, in 1936, was only about 16 yr. Very few records of stream flow were made prior to 1900. Basic data covering periods relatively so short are inadequate for drawing conclusions as to the effect of the works of Man on stream flow, or for determining whether or not the run-off is characterized by significant trends of change through the years.

A study of available precipitation records discloses the fact that, during the period, 1869 to 1934, few 2-day storms, with 6 in. or more of precipitation, occurred in New York State on areas of any considerable extent. In this connection see Fig. 12, which is compiled chiefly from Part V of the Technical Reports of the Miami Conservancy District (1936 revision). The storm of October 8 and 9, 1903, showed a 2-day precipitation in excess of 6 in. at some stations, and, no doubt, other such storms occurred over small areas, but the interesting fact, whatever its significance, is that during this period of 65 yr, for the last 43 yr of which it appears certain that the records were adequate, the State was singularly free from storms carrying heavy precipitation. Except perhaps the Delaware flood of 1903, the history of New York State shows no floods prior to 1935 comparable with the Potomac and Susquehanna floods of 1889, the Ohio Valley flood of 1913, or the Vermont flood of 1927. In spite of storms since 1934, therefore, there seems to be some evidence that New York State, except possibly in its southwestern part, occupies a favored geographic position with respect to the incidence of destructive floods.

THE FLOOD OF JULY, 1935

During the period, July 6 to 9, 1935, heavy thunderstorms accompanied by torrential precipitation occurred in an area in South-Central New York extending roughly eastward from near Hornell, in the northern part of Steuben County, to near Oneonta, in Otsego County. Similar disturbances, generally of a less severe nature, occurred in several other isolated parts of Central and Eastern New York, but the storm's greatest intensity was felt in the area indicated. The fact that the storm centered where it did seems to have had no particular significance, most authorities being agreed that a similar storm might have occurred under the influence of slightly different atmospheric conditions in almost any other part of the State. In most of the area over which the storm centered, all previous 2-day records of rainfall were broken. The maximum official or semi-official 2-day record for this storm was 10.50 in. at Burdett, in Schuyler County, on July 7 and 8, but unofficial records from other points showed precipitation of 12 to 16 in. occurring in as many hours. Unfortunately, the number of reliable precipitation records in the flood area was altogether too small to give an adequate idea of the condi-

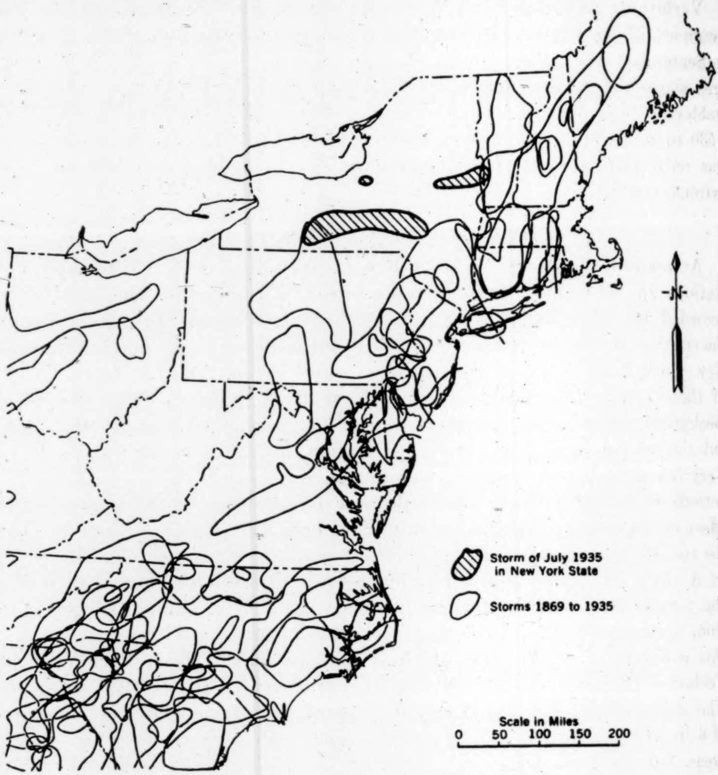

FIG. 12.—LOCATION AND EXTENT OF GREAT 2-DAY STORMS, WITH PRECIPITATION OF 6 INCHES OR MORE

tions, and as the intensity of the storm varied greatly, there is good reason to conclude that greater precipitation occurred at many points than was recorded even unofficially.

One fortunate feature of this storm was that its incidence was such as to cut transversely the main drainage basins of the region in a comparatively narrow zone, with the result that none of the larger streams reached as high a stage as it might have, had the area of the storm been more nearly coincident with its basin. Here, again, there seems to be no reason why the axis of greatest precipitation might not have extended in some other direction than from west to east. Great as the flood damage was, the conditions might conceivably have been such as to produce even more serious results.

The central drainage systems of this region are fed by numerous small streams with generally steep gradients, draining hilly country. Under these conditions and with the extraordinary rainfall, the rate of run-off very quickly approached the intensity of rainfall, and the rise of these streams was very rapid. It was along these small streams that the greatest dynamic damage was done. On the larger streams, losses were caused principally by inundation.

The peak discharges of many small streams with drainage areas of less than 5 sq miles were almost incredibly high (see Fig. 13). There are no gaging stations in the flood area on streams of this size, but subsequent determinations by engineers of the U. S. Geological Survey, using the slope-area method, indicate peak discharges of more than 2 000 cu ft per sec per sq mile. It seems probable that some streams draining 1 sq mile, or less, may have had peak discharges of more than 3 000 cu ft per sec per sq mile. The magnitude of the peak flows was much less in the larger drainage areas, although the Chenango River, near Chenango Forks, draining 1 492 sq miles, broke all existing records with a peak discharge of 82 800 cu ft per sec, or 56 cu ft per sec per sq mile.

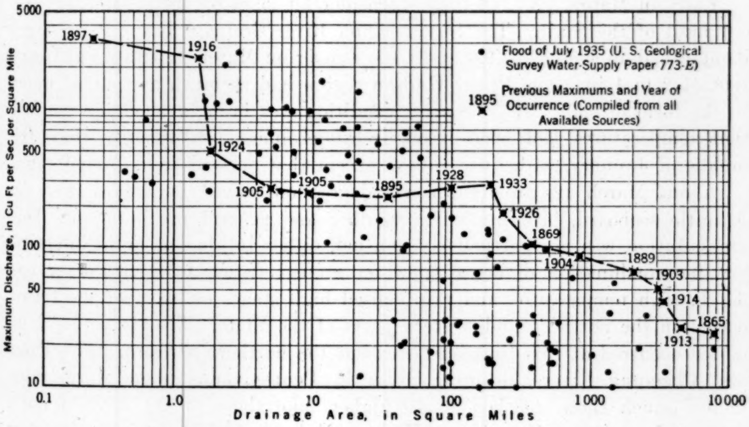

FIG. 13.—MAXIMUM FLOOD DISCHARGES IN NEW YORK STATE.

The outstanding features of this flood, that are of particular interest to engineers, may be summarized as follows:

(1) Large area covered by storm of thunder-storm type.

(2) Unit peak discharges of a magnitude higher than ever before recorded in this part of the United States.

(3) Abnormally heavy and intense precipitation in a hilly country, which caused heavy erosion not only in small stream beds, but even on unbroken hillside surfaces.

(4) Excessive damage in villages situated along small streams, where the encroachment of buildings and other structures restricted the channels and raised the water levels.

(5) Inadequacy of bridge and culvert openings, further complicated by the presence of drift, which resulted in washouts of fills and loss of structures.

(6) Damage by inundation in cities, caused by construction at too low levels, or in unfavorable localities.

A detailed report on the flood of July, 1935, has been published by the U. S. Geological Survey[19].

The Floods of March, 1936

Early in March, 1936, there was considerable snow on the ground throughout most of the State. The Susquehanna River drainage basin above Binghamton had an average of 9.6 in. of snow cover on March 2, with a water content of 2 to 4 in. The Upper Hudson region had as much as 6 in. of water in the form of snow. This general condition was brought about by the fact that temperatures had been below freezing almost continuously since the middle of January, with little run-off except that derived from ground-water.

About March 12, an atmospheric depression moved northward over the Atlantic seaboard, bringing warm weather and general precipitation. This precipitation was not particularly unusual, either in amount or in intensity, but the combination of dense snow on ground frozen to a greater or less depth, high temperature, and rain caused high stages on most of the rivers, except in the northern and western parts of the State. The spring break-up of ice occurred at this time on all except the northern streams. The Tioga and Chemung Rivers, draining areas in Pennsylvania where warm rains melted much snow, reached stages higher than those of the flood of July, 1935. The streams of the Upper Hudson, Mohawk, and Delaware basins were very high. This storm left saturated soils and bank-full streams, and in many sections there was still much saturated snow remaining on the ground.

During the period, March 16 to 19, another atmospheric depression moved slowly northward, bringing from 2 to 3 in. of precipitation. In Central New York this precipitation came as sleet, doing much damage to trees and public utility lines; in the western part of the State it fell as snow. In the southern and eastern areas this rain caused a second flood. Several of the streams in the Mohawk and Upper Hudson drainage basins reached higher stages than during the preceding week and registered new high records at the gaging stations. The high discharges of this second flood were induced largely by the saturated soils, overlying the frost still remaining in the ground, and the relatively high stages still lingering from the first flood.

---

[19] *Water Supply Paper 773-E,* U. S. Geological Survey.

The second storm left much snow in the western part of the State; at Buffalo, for example, there was 18 in. on the ground. Warm weather on March 25 and 26, although unaccompanied by rain, caused rapid melting of this snow, with high run-off in the Genesee and other streams. Such stages, although high, were not record-breaking.

It will thus be seen that in the latter part of March, 1936, three separate and distinct floods occurred in New York State. The northern part of the State cannot be considered in the flood area as, in general, no exceptional records were established there. This is also true, although to a less extent, of the western part of the State. The flood stages were most notable in the eastern part of the State and in the Susquehanna and Delaware drainage basins. Moreover, although many new records were established, especially at gaging stations having short-term records, the March floods in New York State were much less outstanding than those occurring in New England, Pennsylvania, Maryland, and other States. The general statement may be made that no New York stream having a drainage area of more than 400 sq miles showed a peak discharge of more than 50 cu ft per sec per sq mile, and few peak discharges of as much as 100 cu ft per sec per sq mile occurred in drainage areas of less than 400 sq miles.

One important and unusual feature of these floods was the occurrence of two storms in close succession, with a resulting long period of high water. High stages existed for more than two weeks, and the total run-off during that time was very large, amounting in some drainage areas to as much as 10 in. over the entire areas. This fact is pertinent in connection with problems of flood control. As the rains extended over a 10-day period, the high stages on the large streams were more notable than on those of smaller drainage areas.

A comprehensive report on the March floods in the northeastern part of the United States is now (March, 1937) in preparation by the U. S. Geological Survey.

OTHER FLOODS

Prior to the floods of March, 1936, the flood of March, 1913, was generally regarded as the outstanding spring flood in New York State. It was caused by heavy rains on saturated, snow-covered ground. The entire rainfall occurred in two or three days. Record high water was reached in the Hudson, Mohawk, Susquehanna, and some Northern New York drainage basins. If the rain of March 11 to 21, 1936, had been concentrated in two or three days, or even if the two storms of March 11 and 12 and March 17 and 18 had coincided, the conditions would have been more like those of the flood of 1913, but because of the greater rainfall the results would have been vastly more disastrous.

In November, 1927, rains of high intensity fell on saturated ground in New England and to a less extent in Eastern New York. Serious floods occurred at that time on a few New York streams, notably those rising in New England.

Flood Control

One notable example of the value of effective flood-control measures was brought out during the floods of March, 1936.

In 1913 the Hudson River, at Albany, reached a peak of about 225 000 cu ft per sec, and caused great damage in that city. Later, the Sacandaga Reservoir, with a total capacity of 866 000 acre-ft, was created through the construction by the Hudson River Regulating District of the Conklingville Dam, near the mouth of the Sacandaga River, the principal tributary of the Upper Hudson. This reservoir was designed to control with the reservoir full a Sacandaga River flood with a peak flow of 50 000 cu ft per sec, as a peak of about 35 800 cu ft per sec had been reached in March, 1913. The contributing area is 1 044 sq miles.

At the time of the first flood in March, 1936, the Sacandaga Reservoir was nearly empty. On March 18, the computed peak inflow reached 64 600 cu ft per sec, but the entire flood flow was controlled without difficulty. As a result the peak discharge of the Hudson River, at Albany, was held to about 165 000 cu ft per sec, and a repetition of the great losses suffered in 1913 was prevented.

The inhabitants of the area affected by the flood of July, 1935, had the unique and altogether unpleasant experience of being visited by two disastrous floods within less than nine months. Under these conditions it is but natural that there should arise an insistent popular demand for flood control, particularly in this area and, to some extent, in other parts of the State. The subject is a live one in New York State as well as in neighboring States, but there is little evidence that the general public appreciates what is needed to bring about effective flood control or even effective flood protection.

It is recognized that some relief can be afforded by cleaning and straightening channels, by removing structures encroaching upon the streams, and by increasing bridge and culvert openings within reasonable limits. These measures, however, are merely of an auxiliary protective nature. The backbone of successful flood-control operations must be storage. Whether this storage is provided in one large reservoir, or in many small reservoirs on head-water streams, the total capacity must be relatively large if floods like those of March, 1936, are to be rendered harmless. The general public seemingly does not understand that large storage reservoirs require large natural sites, which are too often non-existent. Should not the public be better informed as to the limitations imposed by Nature on flood-control projects?

Many streams have flood-plains of greater or less extent, which carry off flood waters without difficulty. Most flood damage is caused by the fact that Man has not only occupied these flood-plains with his structures, but has encroached on the stream beds themselves. Would it not in some areas, particularly in small villages, be cheaper and more desirable to purchase and remove some of these man-made obstructions to flood flows? The opinion is ventured that flood protection involves a problem in engineering economics that may not always have been adequately considered.

The flood of July, 1935, yielded rates of peak discharge to the square mile which before that time had not been considered possible in New York State, and, to this extent, it has provided a new conception of what may be again encountered in any part of the State at any time. It is a puzzling economic problem to determine on what basis designs for flood-control projects should be made. What are the justifiable economic limits?

These floods have emphasized the importance and value of basic data. More and better precipitation stations are needed—stations equipped with automatic recorders, so that rainfall intensities can be studied. Additional gaging stations should also be established, because the best guide for the future is the experience of the past. Long-continued records of precipitation and stream flow at as many strategic points as possible will furnish a basis for better preparation to meet future great floods as they occur. Such floods may be expected, because there is no valid reason why small areas in any part of the State may not experience storm conditions similar to those of July, 1935, or why major parts of the State may not experience conditions such as existed in New England and Pennsylvania during March, 1936.

FLOODS IN THE UPPER OHIO RIVER AND TRIBUTARIES

BY E. K. MORSE [20] AND HAROLD A. THOMAS,[21]
MEMBERS, AM. SOC. C. E.

SYNOPSIS

The object of this paper is to describe the outstanding characteristics of the unprecedented flood of March, 1936, in the Upper Ohio River and its tributaries, to point out the causes which combined to bring about the occurrence of this flood, and to outline the history of the present flood-control program for these rivers. Recommendations are made for improving the facilities and technique used in forecasting floods in this region.

FLOOD FACTORS

Topography.—The Allegheny and Monongahela Rivers converge at "the Point", in the City of Pittsburgh, Pa., to form the Ohio River. The headwaters of the Allegheny are in the Allegheny Mountains, in Pennsylvania and New York State, and those of the Monongahela River are in the Allegheny and Appalachian Mountains, in Northwestern Maryland and Northeastern West Virginia. The Allegheny River flows in a southerly direction, and the Monongahela, in a northerly direction, both skirting the western foothills of these ranges.

According to the Pittsburgh Flood Commission Report of 1912,

> "The drainage area of the Allegheny River is 11,580 square miles, and that of the Monongahela River is 7,340 square miles, giving a total of 18,920 square miles. * * *
>
> "The area distribution of the combined basins in percent is as follows:

"New York	10%
Pennsylvania	66%
West Virginia	22%
Maryland	2%
	100%

> "The area lying in Pennsylvania is equal to 27.5 per cent of the total area of the State.
>
> "The basins have a greatest length of 290 miles, an average width of about 65 miles and a least width of 46 miles, across the Allegheny at Kittanning.
>
> "The combined area is equal to 9 per cent of the total area of the Ohio Basin, which is 210 000 square miles. * * *
>
> "The principal Allegheny tributaries on the east, 13 in number, have an average length of 47 miles and an average fall per mile of 22.8 feet. The principal tributaries on the west, 10 in number, have an average length of

---

[20] Cons. Engr., Pittsburgh, Pa.

[21] Prof., Dept. of Civ. Eng., Carnegie Inst. of Technology, Pittsburgh, Pa.

37 miles and a fall per mile of 16.7 feet. The Monongahela, on the east has 9 tributaries, with an average length of 45.6 miles and a fall per mile of 31.9 feet; on the west, 7 tributaries, with an average length of 44 miles and a fall per mile of 19.7 feet."

The eastern tributaries of both rivers rise among rough foot-hills at elevations of from 2 300 to 4 800 ft. Those on the west have their source in a high, hilly tableland at elevations of from 1 300 to 2 000 ft.

Although the highest mountains are at the head-waters of the Monongahela, the latter is a mild river even during floods, while in bridge-erection parlance, the Allegheny is a "mad" river. It is, like the Missouri, a treacherous stream; the risk of wash-outs is great during the winter months, and there is no assurance of safety against floods at any time.

It is believed that during the Glacial Period, approximately 75 000 yr ago, the ice flow struck the Allegheny Mountains in Southwestern New York, followed along the Allegheny and Appalachian Mountains, and then followed the Ohio River as far south as Cairo, Ill., depositing enough material in the Eastern Moraine to divert a stream that formerly fed Lake Erie south into what is now the Allegheny. The bluffs of the Upper Allegheny are 700 to 1 000 ft high for many miles, and gradually decrease to a height of 400 to 500 ft at Pittsburgh. The mountains lie within 6 to 10 miles of the stream for many miles at a stretch; their forest cover is gone, the humus is burnt off or washed into the streams, and rocky bluffs are exposed. All these conditions tend to produce rapid run-off.

Rain.—Most of the storms that cause floods in the Upper Ohio basin originate in the Gulf of Mexico. They travel northward up the Mississippi to the vicinity of Cairo, Ill., and thence northeasterly up the Ohio Valley to about Cincinnati, Ohio. From that point they tend to follow one or another of three principal troughs (Fig. 14) which converge at Corry, Pa. Thence, the storms travel in almost an air line to Boston, Mass., and pass into the Atlantic Ocean.

Most of the storms of maximum rainfall travel northeast from Cincinnati. The greatest rain storm of recent years covering a large and continuous area was that of March 23 to 27, 1913, with a rainfall at Dayton, Ohio, of 8.21 in.; Columbus, Ohio, 7.42 in.; Canton, Ohio, 7.39 in.; and Sharon, Pa., 6.56 in. The center of this storm passed 60 miles west of Pittsburgh. On December 14, 1927, a similar storm passed up the Ohio River from Cincinnati to Marietta, Ohio, on the Muskingum River, 297 miles above Cincinnati. Thence, it followed a northerly course through Sharon to Corry, Pa., passing only 40 miles west of Pittsburgh.

The rain storms that bring disastrous floods to Pittsburgh and vicinity are those that continue in an easterly direction from Marietta, swing northeast into the head-waters of the Monongahela River in West Virginia and Northwestern Maryland, and proceed northward along the western foot-hills of the Appalachian and Allegheny Mountains. If the rainfall of March 23 to 27, 1913, or of December 14, 1927, had followed some such path, centering over the Monongahela-Allegheny basin, it would have produced a flood greater than the maximum of record, that of March 18, 1936.

Snow.—In the Allegheny Mountains there is no certainty or regularity in the fall of snow. During the winter of 1907, for example, there was 4 ft of packed snow on the Allegheny Range; in 1909–10 there was 3 ft, which came generally in very light falls; in none of the years from 1930 through 1935 was there more than 12 in. The winter of 1935–36 was unusually cold and severe. The first snow fell early in December, and was followed by frequent heavy falls throughout the season. As late as February 20, 1936, there was 5 ft of light fluffy snow on the range.

FIG. 14.—PATHS OF HEAVY RAINFALL IN UPPER OHIO BASIN.

In the last week of February, a thaw occurred, with temperatures of 50° to 59° F in the Upper Allegheny basin and 60° to 66° F in the Monongahela basin. However, the deep snow had drawn the frost out of the ground, and although about 3 ft of snow melted in the low lands, and most of the heavy ice passed out of both rivers, the flood crest of February 28, at Pittsburgh, was only 29.2 ft (flood stage at that point is 25.0 ft).

Again, during the early part of the winter of 1909–10 the bare ground was frozen to an average depth of about 12 in. before the deep snows of 1910 covered the foot-hills and most of the water-shed of the Allegheny River. On the banks of the Clarion River, one of the two largest tributaries of the Allegheny, there was 3 ft of frozen snow. In the early part of March, 1910, the temperature rose, and remained above 40° F continuously for nine days.

Meanwhile, mist and rain fell constantly. A big flood on the Allegheny was predicted. Yet the maximum stage during this thaw and break-up was barely above the flood stage of 25 ft. The blanket of snow had drawn out the frost and had acted as a sponge, holding back the mist, rain, and thawing frozen snow.

Nevertheless, the melting of snow contributes to flood stages, and is always a menace. When there is a blanket of snow, a thaw and a heavy rain storm coming together can produce a flood-stage of more than 30 ft at Pittsburgh. This combination of snow, ice, hard rains, and mild weather was, in fact, the cause of the flood of March 18, 1936, with a stage of 46 ft—the greatest of record at that point.

Ice.—Navigation on the Ohio River as far as Pittsburgh usually continues during the winter months. One of the writers recalls seeing loaded horse-drawn sleds crossing the Ohio on ice from East Liverpool, Ohio, to Newell, W. Va., on December 17, 1904, but such a condition is rare.

One of the severest winters on record was that of 1936. The Allegheny and Monongahela Rivers froze over on December 26, 1935, and by February 21, 1936, there was clear hard ice of a thickness of 20½ in. on the Allegheny and 18½ in. at Lock No. 7, on the Monongahela, 52.6 and 82.3 miles, respectively, from "the Point", in Pittsburgh. It is believed that clear ice froze to a thickness of at least 24 in. in the Upper Allegheny, but no authentic records have been obtained. A similar condition has never been recorded in this section of the United States.

This great body of clear ice with a blanket of deep snow presented a flood menace of unprecedented nature. It was providential that the ice went out of both rivers (except from the head-waters of the Allegheny) on the minor crest of February 28, instead of during the record flood that occurred just nineteen days later.

Forests.—The 1912 report of the Pittsburgh Flood Commission contains descriptions and maps of a large acreage of virgin forest in the Allegheny and Appalachian Mountains. This forest was especially dense in the headwaters of the Allegheny, where there was a fine stand of white pine in eight counties in Northern Pennsylvania and good stands in New York State. In 1937, the only virgin forests left are Federal-and State-owned tracts that include a few parks. The Commonwealth of Pennsylvania has been purchasing forest lands for years, and on October 1, 1934, the State-owned forest land amounted to 1 649 430 acres. In addition, the Game Commission of Pennsylvania has purchased 547 406 acres of forest land for sanctuaries and has turned it over to the possession and protection of the Commonwealth. The Weeks Bill, passed by the Federal Government in 1911, contemplated the purchase of 726 340 acres in Northwestern Pennsylvania to be known as the Allegheny National Forest. By April 26, 1936, forest and surface rights to about 70% of this land had been acquired by the Government.

Notwithstanding the fact that the Federal and State Governments maintain fire towers throughout these areas, and are thoroughly equipped to fight forest fires, the latter remain the greatest cause of forest destruction and the greatest hindrance to reforestation of unproductive farm lands.

Run-Off.—When the flood of March 15, 1907, came it was freely predicted that it would not be equalled for 100 yr. The engineers of the Pittsburgh Flood Commission, however, did not foresee that the day would soon come when disastrous floods would be caused by the carelessness of Man. They did not realize that the virgin forests would disappear so soon, nor that the time would ever come when hundreds of men would be sent into the upper water-sheds to clear and burn great tracts of fallen, dead trees, to locate and construct dirt highways through the mountains, and all but make parks out of the wilds.

To-day, the virgin forests are all but gone. There are thousands of miles of improved highways and scores of mountain parks; and fishermen, hunters, and careless campers are here, there, and everywhere. The lighted cigarette tossed away by the criminally careless smoker has caused a great increase of timber and land fires that have left in their wake destroyed forests and burnt humus—humus that it will take centuries to replace. Hence, the Man-made floods.

THE UNITED STATES WEATHER BUREAU

Every day of the year other than Sundays and holidays the Pittsburgh Office of the U. S. Weather Bureau publishes a weather map issued by the U. S. Department of Agriculture, giving a forecast for Pittsburgh and vicinity, together with observations taken at 8:00 A. M. It is supplemented by a card giving data on river conditions at various points. About 448 maps and from 86 to 100 river bulletins are mailed daily for local guidance.

The force of the local office has been proficient, accommodating, and of untold value to the public, especially to the river interests and navigators. It is with keen regret, therefore, that it must be recorded that on March 16 and 17, 1936, the local office failed utterly to predict the disastrous flood that was sweeping down both the Allegheny and the Monongahela Rivers, until it was too late to cope even partially with the onrushing tide.

A study of the previous maximum flood of record (1907) and that of 1936 reveals that in both cases the U. S. Weather Bureau either was ignorant of the volume of snow in the mountains at the head-waters of the Allegheny and Monongahela Rivers, or did not appreciate that snow is always a flood menace during March.

The following data are abstracted from the Weather Bureau observations and predictions for three days in March, 1907:[22]

March 13, 1907, Observations at 8:00 A. M.:

Maximum temperature in preceding 24 hr, in degrees Fahrenheit..	57
Minimum temperature in preceding 24 hr, in degrees Fahrenheit..	49
Rainfall in preceding 24 hr, in inches..........................	1.46
Stage of rivers at Point, in feet..............................	26

---

[22] In 1907, zero stage was at Elevation 696.8 above mean tide.

March 14, 1907, Observations at 8:00 A. M.:

Maximum temperature in preceding 24 hr, in degrees Fahrenheit	58
Minimum temperature in preceding 24 hr, in degrees Fahrenheit	33
Rainfall in preceding 24 hr, in inches	0.68
Prediction made at 3:30 A. M. (of crest stage at Point), in feet	31
Warning issued at 9:00 P. M. (for crest stage), in feet	34

March 15, 1907, Observations at 8:00 A. M.:

Maximum temperature in preceding 24 hr, in degrees Fahrenheit	46
Minimum temperature in preceding 24 hr, in degrees Fahrenheit	31
Rainfall in preceding 24 hr, in inches	0.00
Flood crest, 2:15 A. M. (writers' record), in feet	35.5

Similar data from the observations and predictions for March, 1936,[28] are as follows:

March 16, 1936, Observations at 8:00 A. M.:

Maximum temperature in preceding 24 hr, in degrees Fahrenheit	45
Minimum temperature in preceding 24 hr, in degrees Fahrenheit	37
Rainfall in preceding 24 hr, in inches	0.91
Stage of rivers at Point, in feet	19.8

March 17, 1936, Observations at 8:00 A. M.

Maximum temperature in preceding 24 hr, in degrees Fahrenheit	40
Minimum temperature in preceding 24 hr, in degrees Fahrenheit	32
Rainfall in preceding 24 hr, in inches	1.68
Stage of rivers at Point, in feet	24.7
Prediction, 8:00 A. M., for forenoon of March 18, in feet	32 to 33

March 18, 1936, Observations at 8:00 A. M.:

Maximum temperature in preceding 24 hr, in degrees Fahrenheit	34
Minimum temperature in preceding 24 hr, in degrees Fahrenheit	30
Rainfall in preceding 24 hr, in inches	0.72
Stage of rivers at Point, in feet	42
Prediction (made at 8:00 A. M.) of crest stage, in feet	43.5
Crest reached at 9:00 P. M., in feet	46

Something important was lacking in the Weather Bureau in 1907. It was still lacking in 1936, when the prediction of March 17 was 10 ft in error, and that of the following morning still under-estimated the crest by 2.5 ft. Why these errors?

During the week preceding the flood of March 15, 1907, one of the writers crossed the Tussey Mountains, 16 miles east of Tyrone, Pa., in two places, at elevations of 2 100 and 2 200 ft, respectively. There was about 12 in. of packed snow at the foot of the mountains and 48 in. of light fluffy snow on the summit, equivalent, say, to 4.8 in. of rain. The run-off at that time and place was 70 to 80 per cent.

---

[28] In 1936, zero stage was at Elevation 694.0 above mean tide.

Immediately before the thaw of February 24, 1936, which resulted in the flood of February 28, of 29.2 ft, the personal records of one of the writers show that there was 60 in. of light fluffy snow on the crest of the Tussey Mountains. As mentioned previously, it happened that no floods came from the 3 ft of melted snow. However, there was 3 ft of packed snow at Cresson, Pa., at the head-waters of the Conemaugh River in the Allegheny River basin, and about 5 ft on the top of the Allegheny Mountains, which did contribute to the flood of March 18.

The thirty-five local Weather Stations in the Allegheny-Monongahela basin reported the snowfall in their daily reports, but gave only meager data regarding the amount of snow on the ground. This deficiency in the record is in part due to the fact that the majority of the stations are in cities and towns instead of in rural districts. However, the primary reason for the deficiency is that the pay of recorders is rediculously small. The pay per month for reporting the weather, daily, is $10. For rainfall reports the observers are paid at the rate of 50 cts per in. of rain.

The Pittsburgh Office of the Weather Bureau claims that it failed to receive many reports from stations along the Allegheny and Monongahela Rivers on account of broken communications by telephone and wire. It is also stated that those stations are manned by agents having other jobs and that the $10 is so much "extra money." There are twelve such weather stations and six rainfall observation stations in the Allegheny basin. The U. S. Army Engineers report the weather and rain conditions to the Weather Bureau from the locks and dams on the Allegheny and Monongahela Rivers and down the Ohio as far as Wheeling, W. Va., without cost.

The local U. S. Weather Bureau Office erred in its predictions for March 15, 1907, and March 18, 1936, for the one and simple reason that it failed to receive adequate weather and rain reports.

The time has long since come when the Pittsburgh Metropolitan Area should be served by adequate weather stations along the Allegheny and Monongahela Rivers and their main tributaries, each fully equipped with modern appliances and manned by a competent employee on a yearly salary. Properly equipped stations should also be established in the mountains, at 50-mile intervals from the Southern Appalachians to the Northern Alleghenies. The observer at each mountain station should be a young, healthy man, preferably a graduate forester.

All stations, both along the rivers and in the mountains, should have private broadcasting outfits, and the mountain stations should broadcast data at stated periods so the public could also listen in. If the local U. S. Weather Bureau Office had known the actual conditions in the mountains on March 16, 1936, and had had the benefit of frequent, accurate, radio reports, forecasts and warnings could have been issued to the public in ample time to have prevented at least $100 000 000 of the loss that occurred in Pittsburgh and vicinity on March 18. A 24-hr notice of the flood would have saved one single department store, for example, from a direct loss of between $750 000 and $1 000 000.

Three great navigable rivers flow through Pittsburgh, the tonnage on one of them, the Monongahela, being greater than that on any other inland river in the United States.

The railroad tonnage over bills of lading in Pittsburgh is the greatest of any city in the country.

Three Federal trunk-line highways, and many highways of less importance, pass through the community.

The direct recorded loss from the flood of March 18, 1936, in the City of Pittsburgh was equal to the total flood loss in 1936 in any one State except Pennsylvania.

Notwithstanding all these facts, the facilities furnished the Pittsburgh Office of the U. S. Weather Bureau for obtaining intelligent reports from the Allegheny and Monongahela Rivers are pitifully meager. This situation is a disgrace. Pittsburgh's most disastrous flood is yet to come.

If the local Weather Bureau continues to be "starved" financially, and is not equipped by intelligent salaried men for reporting weather and rain conditions throughout the 19 000 sq miles of the contributing water-shed, then the entire Weather Bureau should be taken out of the Department of Agriculture and become a department under the jurisdiction of the Chief of Engineers, U. S. Army.

Pittsburgh Floods

There have been eighty-six floods in Pittsburgh since 1856—somewhat more than one per year. According to estimates compiled by the writers the local flood losses during the three decades prior to 1936 have averaged about $2 000 000 annually. The two floods most disastrous to the Pittsburgh District have already been indicated as those of 1907 and 1936.

Flood of 1907.—At its crest of 35.5 ft,[24] the flood of March 15, 1907, inundated 52% of the "Golden Triangle," the 218-acre central business section. The direct loss to Pittsburgh and its immediate vicinity amounted to $6 000 000, and the property and indirect loss was placed at $50 000 000. The supply of water, heat, and light, and most of the local transportation facilities were maintained, although the steam railroads were paralyzed for three days.

Prior to this flood there was considerable snow on the head-waters of the Allegheny and Monongahela Rivers, but on account of the low temperature its thawing was not the main contributing factor. Between March 12 and March 15, rainfall was general over the entire tributary basin. Precipitation varied from 0.20 in. to 3.25 in. on the Allegheny water-shed and from 1.50 in. to 4.25 in. on the Monongahela water-shed. The crests of the two streams reached the Point 2 hr and 15 min. apart. Had they coincided, it is estimated that they would have produced a flood stage of 40 ft[24] at Pittsburgh.

Flood of 1936.—The flood of 1936 reached its crest during the night of March 17–18, at which time 62.4% of the Golden Triangle was under water. The basements of all the office buildings below Smithfield Street and Upper Grant Street were flooded. All power, elevator, and electric service was shut down. No one was allowed to pass the Federal guard lines into the "Golden Triangle" without a permit from the Director of Public Safety. The business of the city was paralyzed for ten days. Fortunately, so thorough were the regulations of the State Board of Health and the City Department of Health that no epidemic followed the flood in the city and vicinity, and no appreciable increase occurred in the normal death rate.

---

[24] Based on zero stage at Elevation 696.8 above mean tide.

No precise estimate is available covering both the direct and indirect damage to the Pittsburgh District during this flood. A preliminary estimate by the Pittsburgh Chamber of Commerce placed the damage at about $200 000 000. No estimates have been made of the losses that occurred between the sources of the Allegheny and Monongahela Rivers and the Point, although hardly a town escaped great damage. The disaster also continued down the Ohio River 968 miles to Cairo Ill.

It is impossible to describe the distress suffered on that memorable day of March 18, 1936, especially among the poorer classes, who lost their meager all along a river-bank frontal of more than 1 000 miles. One illustration, out of thousands that could be cited, must suffice. Sharpsburg, Pa., is a little suburb of Pittsburgh, on the right bank of the Allegheny, 6.7 miles above the Point. When the flood waters had receded sufficiently to start shoveling out the mud from hundreds of homes of the middle and poorer classes so many pianos and pieces of furniture and other household goods were dumped on the sidewalks and streets to be hauled away and destroyed that transportation on the highways was blocked.

As to the causes of the flood: The severe winter and heavy snowfall of 1935–36 have already been mentioned. After the minor flood of February 28, the rivers dropped. From March 1 to March 15 mild weather prevailed; the average temperature was 39° and the total rainfall during the period was 1.28 in. The average river stage was 19 ft. All signs pointed to a mild break-up of winter, with the thermometer reaching 61° on March 15 and the river gage at the Point recording 20.8 ft.

General rains began the next day, however. Precipitation on March 17 and 18 varied from 1.33 in. to 3.76 in. on the Allegheny water-shed and from 2.17 in. to 3.79 in. on the Monongahela. The crest of the Monongahela flood reached the Point at 6:00 P. M. of March 17, and that of the Allegheny arrived three hours later, the Monongahela meanwhile remaining stationary.

The Allegheny River flows faster than the Monongahela, and the fact that the crest of the latter generally reaches the Point first can be accounted for by the shorter length of the stream and by the fact that storm centers usually pass over the head-waters of the Monongahela several hours before reaching the drainage basins of important feeders of the Allegheny.

It is a striking coincidence that the Kiskiminetas River, emptying into the Allegheny River 40 miles north of Pittsburgh, and the Youghiogheny River, joining the Monongahela River 15 miles south of that city, should have supplied the major part of the flow at the crest of both the 1907 and 1936 floods. The rapid travel of the flood crest is especially pronounced in the Youghiogheny, which is a rapidly flowing stream from source to mouth.

The Possibility of Greater Floods

The disastrous flood of 1936, has opened deaf ears, and has quickened the conception of the importance of adequate flood control. The public has come to realize that actual damages were only a fraction of the loss that might have occurred. It may seem absurd to suggest that Pittsburgh is a lucky city, but it is a fact.

Many of the conditions that tend to produce a disastrous flood are present in the drainage basin of the Allegheny and Monongahela Rivers. Among these conditions may be mentioned: (1) Steep summit approaches of the Allegheny and Appalachian Mountains; (2) high percentage of run-off; (3) rapid fall of stream beds; (4) ground frozen 1 ft to 3 ft before deep snow falls; (5) severe winters; (6) deep snows every four to six winters; (7) thick ice every five to eight winters; (8) warm spells either the latter part of February or early in March; and (9) hard rains coming about March 15 to 20.

The combined incidence of these conditions was illustrated in the flood of 1936, but not to the fullest possible extent. For example, according to estimates by the writers:

1.—If the rain of March 17–18, 1936, had not turned into snow above Oil City, Pa., the flood crest stage at the Point on March 18 would have been at least 48 ft.

2.—If the great rainfall of March 23 to 27, 1913, had centered over the drainage basin of the Monongahela and Allegheny Rivers instead of about 60 miles west of the basin, the flood height at the Point would have reached 48 ft.

3.—On December 14, 1927, there was a flood of 30.2 ft at the Point. If the rain storm on that date had passed over the drainage area of the Monongahela and Allegheny Rivers, instead of 40 miles west of the Point, the crest would have reached 45 ft.

4.—In 1936, if the thick ice that came out in the break-up of February 16 and 17 had combined with the floods of February 28 and March 18, the crest would have reached 54 ft.

It is of interest to examine one such possibility in detail. If the floods of February 28 and March 18 alone had combined, there would have been a flood of 54 ft at the Point, with enough ice left in the head-waters to form heavy gorges. The ice in the Allegheny River might first have swept the Highland Park Bridge off its foundations, and then the Sharpsburg Bridge. Next, it might have gorged on Herrs Island, and after doing great damage there, might have broken and moved down through the 16th Street and Pennsylvania Railroad Bridges, only to lift the 9th Street Suspension Bridge off its piers, causing it to turn over and hold the ice gorge like an umbrella in a wind storm.

Before the anchorages of the bridge were stressed to the breaking point, the ice might have been packed solid to the bed of the river and piled up from 15 to 20 ft above the flood height at that time. It would soon have extended to the concrete wall of the elevated section of the Pennsylvania Railroad on the North Side, and by that time the flood in the Golden Triangle would have reached the appalling height of 55 to 60 ft, and the Allegheny River would have been discharging its flood water through the center of the city.

What damage the thick clear ice, rushing through the main streets, would have done to the old buildings and even to the modern sky-scrapers is difficult to state. Its impact against the walls at a velocity of from 8 to 12 ft per sec would certainly have wrought untold damage and destruction. It is certain that most of the old buildings would have quickly collapsed, and this collapse, in turn, would have menaced the stability of the modern buildings. The loss of life and destruction of property would have been appalling. This is no fantastic imagination, but a conclusion which is the product of many years of technical experience in the field. Pittsburgh, the "Lucky City," may some day have such a combination of floods. The following tabulation shows the estimated maximum discharge at Pittsburgh that would have resulted from a combination of the floods of February 28 and March 18, 1936. It is based on gage readings taken March 18, on the tributaries of the Allegheny and Monongahela Rivers:

Estimated Maximum Discharge at Pittsburgh, from the:	Cubic Feet per Second
Allegheny River	473 000
Monongahela River	322 000
Total at Pittsburgh	795 000

This discharge represents a gage height of 54 ft at the Point, according to the extended revised rating curve for Pittsburgh of June, 1936. It is equivalent to a run-off rate of 41.5 cu ft per sec per sq mile, which is 25% in excess of the tabular value published by the Commonwealth of Pennsylvania for a drainage area equal to that of Pittsburgh. The actual run-off rate on March 18, at Pittsburgh, was 97% of the tabular value. The run-off rate on the Susquehanna River, at Harrisburg, Pa., during the same flood, was 21% in excess of the tabular value.

PROPOSED PLANS FOR CONTROLLING FLOODS

Although it is not the intention of the writers to enter upon an elaborate description and analysis of the various groups of retarding reservoirs that have been proposed for flood protection on the Allegheny-Monongahela River System, a brief discussion of the nature and action of these reservoirs is pertinent.

The history of floods in the Pittsburgh District begins in 1754, when George Washington, then a young man, nearly lost his life while crossing the flooded Allegheny River on an improvised raft. The site of this occurrence is now marked by the "Washington Crossing Bridge" at 40th Street, in Pittsburgh. Since then, the problem of controlling floods on the Allegheny and Monongahela Rivers has been discussed on many occasions, but it was not until early in the Twentieth Century that the population and wealth in these river valleys increased sufficiently to justify serious consideration of a comprehensive program of flood control by reservoirs. The flood of March, 1907, rising to a stage of 38.5 ft (based on present pool level) at Pittsburgh, furnished the impetus for the creation of the Flood Commission of Pittsburgh.

This was essentially a citizen's committee, organized under the auspices of the Chamber of Commerce. The Engineering Committee of the Flood Commission, at the time of the publication of its voluminous report of 1912, was as follows: E. K. Morse, M. Am. Soc. C. E., *Chairman;* the late Emil Swensson, M. Am. Soc. C. E.; the late William Glyde Wilkins, M. Am. Soc. C. E.; George S. Davison, Past-President, Am. Soc. C. E.; the late Paul Didier, M. Am. Soc. C. E.; the late Julian Kennedy; the late Morris Knowles, M. Am. Soc. C. E.; and George M. Lehman, M. Am. Soc. C. E., Engineer in Charge. The Principal Assistant Engineer was Kenneth C. Grant, M. Am. Soc. C. E.

Funds for the work of the Flood Commission were obtained by asking the owners of property affected by floods to contribute at the rate of 1 mill per dollar of assessed valuation. Substantial contributions were made by the City of Pittsburgh and the County of Allegheny. A total of approximately $124 000 was expended from 1908 to 1911 in carrying on extensive surveys and investigations, and a publicity campaign.

The first engineering investigations of the Commission were predicated on the assumption that flood protection would be secured primarily by the construction of river walls. Thorough surveys were made of the river channels within the city limits of Pittsburgh, and hydraulic and economic studies were made to determine the feasibility and cost of such walls, and to establish their most desirable location. It developed from these studies that serious difficulties and uncertainties would be encountered in designing a wall which would provide flood protection without the assistance of reservoirs or channel improvement.

As the work progressed, the possibility and advantage of securing flood control by reservoirs on the head-waters and tributaries of the rivers became more and more apparent, and later investigations included extensive surveys of numerous reservoir sites scattered over the drainage area of about 19 000 sq miles above Pittsburgh. The selection of these sites was based on a reconnaissance including every tributary with a drainage area of more than 50 sq miles. The studies included detailed analyses of costs, and of the flood-lowering effect of various groups of reservoirs. They also developed the possibility of using part of the reservoir capacity to regulate the dry-weather flow of the rivers in the interest of navigation, sanitation, hardness control, and acidity control.

The ingenuity and thoroughness of the hydraulic studies can be admired even after the lapse of a quarter century that has seen great advances in the technique of flood control by reservoirs.

FIG. 16.—ELEVEN-RESERVOIR SYSTEM PROPOSED BY CORPS OF ENGINEERS, U. S. ARMY, IN 1928

The Flood Commission secured the establishment of numerous stream-gaging stations and rainfall gages. It collected a great mass of information on matters directly and indirectly related to flood control, such as stream flow, rainfall, topography and geology, forestation and agricultural development, location of coal, gas, and oil fields, railroads and other transportation lines, flood damages, and industrial developments. This information, together with the engineering studies and conclusions of the Commission, was set forth in the report of 1912. The final recommendations of the Commission proposed that seventeen reservoirs be constructed on the head-waters or tributaries of the Allegheny and Monongahela Rivers, for the primary flood protection of all communities and industries on the banks of these rivers. The location of these reservoirs is shown in Fig. 15. Flood walls were also recommended as a secondary line of defense.

In order to convey some idea of the merits of the seventeen-reservoir system of the Flood Commission, in comparison with reservoir systems subsequently proposed, it is desirable to review the general topographical and industrial conditions governing the selection of reservoir sites in Western Pennsylvania.

Although the sources of the Allegheny and Monongahela Rivers and many of their tributaries are in the high mountains that border the eastern edge of the combined drainage basin, the major reaches of the main rivers and their larger tributaries are located in the Allegheny Plateau. The even and horizontal skyline of this plateau shows it to be a plain which has been elevated in comparatively recent geologic times. Since this elevation, the rivers and streams of the region have carved a fully developed drainage system of deep and narrow valleys. In the Pittsburgh region, where the characteristic topography is clearly developed the main valleys have a depth of 400 to 500 ft below the hill tops.

The rocks composing the plateau consist, in general, of the soft sandstones, shales, and coal seams of the Pennsylvanian period, and are bedded nearly horizontally, with a gentle dip to the southwest. This dip causes the main river channels to lie to the west of the median line of their drainage basin, so that the tributaries entering from the west are shorter and less numerous than those entering from the east. In general, the rock structure of the Allegheny Plateau is remarkable for the absence of hard and erosion-resistant strata. The lack of such strata causes the gradients of the larger streams to be uniform over long distances, to the joy of the railroad engineer and the despair of the water-power engineer. The absence of waterfalls, canyons, or gorges on the main rivers of such a rugged region is unusual and striking. Except in its extreme northwestern part, the region is not glaciated, and, in general, rock strata are exposed in the river beds or have only a shallow cover. (The latter statement does not apply to the glaciated region or to of glacial gravel.) Because of these topographic characteristics, one might the main channel of the Allegheny River, which contains an outwash train say that on a typical river or stream of this region every cross-section is a potential dam site. In so far as natural conditions are concerned, no site has outstanding advantages over numerous other sites on the same stream. In this district the engineer cannot hope to find a canyon dam site lying below a broad flat valley. If topography were the only factor to be considered, it would be correct to state that storage in this region is very easy to obtain, but expensive per acre-foot.

The great obstacle to the construction of retarding reservoirs on the rivers of Western Pennsylvania is furnished not by Nature but by the works of Man; namely, railroads and industrial developments. Several great trunk railroad lines and many branch railroads follow the easy and uniform grades of the river valleys. In the lower and more densely settled parts of the main valleys, it is almost impossible to displace or relocate the railroads or to build a dam of any height without interfering with important industries and communities. Farther up stream there are sites where a branch railroad can be shifted to an adjacent valley, or where a main railroad can be elevated above a proposed reservoir flow line, although at enormous expense. These considerations are of paramount importance in the selection of reservoir sites.

TABLE 8.—Data on Reservoirs in Seventeen-Reservoir Project Proposed by the Flood Commission of Pittsburgh in 1912

Reservoirs*	Controlled drainage area, in square miles	Storage Capacity			Percentage of main basin controlled
		In acre-feet		In inches of run-off	
Allegheny Basin:

* For location, see Fig. 15.

Of the seventeen reservoirs recommended by the Flood Commission of Pittsburgh, thirteen were located in the Allegheny basin and four in the Monongahela basin. A summary of data regarding these reservoirs is given in Table 8.

Among the excellent features of this system of reservoirs may be mentioned the large percentage of controlled area, and the good distribution of sites throughout the basin. The degree of protection afforded by this system agrees well with the economic limit of protection determined by more recent studies. The design and location of the dams made them well adapted to the storage of April, May, and June run-off to increase the minimum stream flow during the dry months of the summer and fall. The wisdom of not attempting to develop hydro-electric power at the flood-control reservoirs has been confirmed by subsequent studies.

The occasion for subsequent revision of the original seventeen-reservoir plan arose primarily for two reasons:

(1) Among the largest and most effective reservoirs of the system were those on the Clarion and Cheat Rivers. The former river is the second largest tributary of the Allegheny and the latter is the second largest tributary of the Monongahela. After 1912 the Associated Gas and Electric Company constructed the Piney Hydro-Electric Plant on the Clarion River, and the West Penn Power Company constructed the Lake Lynn Hydro-Electric Plant on the Cheat River. These Companies, it is said, also own property rights in many or in all undeveloped reservoir sites on the respective rivers and have plans for the future power development of these rivers by chains of reservoirs extending from source to mouth. Among the flood-retarding reservoirs recommended by the United States Engineers since 1928 there are none on the Clarion and Cheat Rivers. This indicates a conclusion that existing and proposed hydro-electric developments have eliminated the possibility of constructing flood-retarding reservoirs on these streams. The writers do not concur in this conclusion. They consider that flood protection for the great industrial district of Western Pennsylvania is of such paramount importance as to justify, if necessary, the use of condemnation proceedings to acquire flood-control-reservoir sites on the Clarion and Cheat Rivers. Such proceedings although conducted in the public interest, would give full consideration to the legal rights of the Power Companies. The reservoirs would be among the most valuable and effective ones of the entire system. For some years, the Pennsylvania Water and Power Resources Board has refused to grant permits for further power developments on the Clarion River, because of the fact that public welfare might require the development of one or more sites on this river for flood-control purposes. For these reasons, the writers believe that no final program for flood protection in the Allegheny-Monongahela Valley should be adopted until additional consideration has been given to the development of flood storage-reservoir sites on the Cheat and Clarion Rivers.

(2) The Flood Commission's original plan contained several reservoirs having a storage capacity equivalent to less than 2 in. of run-off from the

controlled water-shed. This capacity is only about one-third or one-fourth of that required to absorb the entire run-off of the water-shed during a great flood. Advances in the art of flood-control engineering have made it evident that the storage of a retarding reservoir can be designated as of "superior" nature only if the reservoir is capable of absorbing completely, or almost completely, any flood that may originate above it. Storage of less amount than this must be regarded as of 'inferior" nature, because of the possibility that the reservoir may be operated so as to fill during the early period of a great flood and before the arrival of the crest. For such a reservoir, it is not possible to set up an operating schedule that will avoid this difficulty in a satisfactory manner. If the reservoir is operated for safe control of the largest floods, it will be very ineffective in smaller floods, and *vice versa.* In the light of more recently acquired knowledge it appears best, therefore, to modify the Flood Commission's original plan so as to substitute storage of a superior type for that of an inferior type.

Although the work of the Flood Commission was supported by influential and public-spirited citizens, many years were spent in an unsuccessful attempt to arouse the public to take the necessary legislative and financial steps to bring about the actual construction of the reservoirs. If another disastrous flood had occurred within a few years after the publication of the 1912 report, it is probable that the reservoirs would have been built. However, the great storm of March, 1913, which caused such terrible damage on the lower tributaries of the Ohio River, did not produce excessively high stages on the Allegheny and Monongahela Rivers, and for the following quarter century, no flood of extraordinary nature occurred on these streams.

In 1927, that portion of the work of the Flood Commission dealing with protection by river walls was reviewed and amplified by the City of Pittsburgh. The Department of Public Works prepared detailed plans for a river wall extending along the front of the Golden Triangle and along a considerable length of the banks of the Ohio River within the city limits. These plans proposed the deepening of the rivers by dredging and also provided for terminal wharves, boulevards, and other civic improvements associated with the river walls. Accurate hydraulic studies were made to determine how flood heights would be affected by the proposed improvements. Before the completion of the report on these studies, the work was brought to a close by conditions arising within the City Administration.

Within the past decade the engineering supervision of flood-protection studies in the Pittsburgh region, as in other parts of the United States, has passed from private engineers to the engineers of the United States Army. Moreover, the old idea that each community or group of communities should pay in full for its own flood protection is being cast aside by the public in favor of Federal financing. These considerations have terminated the technical labors of the Pittsburgh Flood Commission.

Through the efforts of the Flood Commission, an appropriation of $50 000, one-half from the State of Pennsylvania and one-half from the Federal

Government, was obtained in 1924 to re-study the flood-protection problem and to bring up to date all previous studies. This work was delegated to the United States Engineers, who, after making extensive surveys, designs, and investigations, submitted their findings in a report dated 1928. In March, 1937, this report was still unpublished, but it is said to have furnished the physical basis for the several subsequent reports by the United States Engineers on the same subject. It is the understanding of the writers that none of these subsequent reports is based on surveys and studies that can compare in elaborateness and completeness with those of the report of 1928.

The report of 1928 recommended the construction of eleven reservoirs: Eight in the Allegheny basin and three in the Monongahela basin. The location of these reservoirs is shown in Fig. 16, and pertinent data are given in Table 9.

It is to be noted that the total storage of this eleven-reservoir system is almost twice that of the original seventeen-reservoir system of the Flood Commission. The individual dams are much higher, and their storage is definitely of the "superior" type. In the 1928 report it is stated that this eleven-reservoir system would reduce future flood damage to a negligible amount on the Allegheny and Monongahela Rivers and on a limited reach of the Upper Ohio River. The estimated total cost was $96 378 000. The proposed dams would be equipped with manually controlled gates to permit the conservation of the spring run-off. No hydro-electric power development is contemplated at the reservoirs.

TABLE 9.—DATA ON RESERVOIRS IN ELEVEN-RESERVOIR SYSTEM PROPOSED BY THE CORPS OF ENGINEERS, UNITED STATES ARMY, IN 1928

Reservoirs*	Controlled drainage area, in square miles	STORAGE CAPACITY		Percentage of main basin controlled
		In acre-feet	In inches of run-off	
Allegheny Basin:				
French Creek	541	140 000	4.8	4.66
Allegheny	2 190	930 000	7.96	18.9
Tionesta	483	133 000	5.17	4.16
Red Bank	460	143 000	5.83	3.96
Mahoning	327	79 000	4.53	2.82
Crooked	278	95 000	6.4	2.4
Conemaugh	1 427	283 000	3.72	12.3
Loyalhanna	267	79 000	5.55	2.3
Total, Allegheny Basin	5 973	1 882 000	5.93	51.4
Monongahela Basin:				
Youghiogheny	1 020	340 000	6.2	13.9
Tygart	1 220	327 500	5.04	16.6
West Fork	366	62 500	3.2	5.0
Total, Monongahela Basin	2 606	730 000	5.27	35.5
Total, both basins	8 579	2 612 000	5.72	45.3

In studying this system, the following comparison between certain features of the Allegheny and Monongahela Rivers, will be of interest:

Comparison of Head-Waters.—

Allegheny River.—There is a favorable site for a large reservoir on the head-waters of the main river (Allegheny Reservoir, 10 miles above Warren, Pa.). It contains no important towns or industries, and a single-track railroad running through it can be diverted to another valley.

Monongahela River.—There is a favorable site for a large reservoir on the head-waters of the main river (Tygart Reservoir, 3 miles above Grafton, W. Va.). It contains no important towns or industries, and a single-track railroad running through it can be diverted to another valley.

Comparison of Largest Tributaries.—

Allegheny River.—The Kiskiminetas River, its largest tributary, enters a short distance above Pittsburgh, Pa., and has an extremely important effect on floods. The valley is completely occupied by a main railroad line with heavy traffic (Pennsylvania Railroad Freight Line). A favorable site for a large reservoir is 1 mile above Saltsburg, Pa. A railroad relocation above the proposed reservoir level is physically feasible, but would be enormously expensive.

Monongahela River.—The Youghiogheny River, its largest tributary, enters a short distance above Pittsburgh and has an extremely important effect on floods. The valley is completely occupied by main railroad lines with heavy traffic (Baltimore and Ohio and Western Maryland). A favorable site for a large reservoir is 2 miles below Confluence, Pa. A railroad relocation above the proposed reservoir level is physically feasible, but would be enormously expensive.

Next Largest Tributary.—

Allegheny River.—The Clarion River, the second largest tributary, enters at a moderate distance above Pittsburgh. It has been considered unavailable for flood control because of an existing large hydro-electric plant (Piney), with other reservoir sites controlled by a power company. The writers do not concur in this conclusion. A flood-storage reservoir on this river would be of immense value in a flood-control system.

Monongahela River.—The Cheat River, the second largest tributary, enters at a moderate distance above Pittsburgh. It has been considered unavailable for flood control because of an existing hydro-electric plant (Lake Lynn), with other reservoir sites controlled by a power company. The writers do not concur in this conclusion. A flood-storage reservoir on this river would be of immense value in a flood-control system.

Smaller Tributaries.—

Allegheny River.—Favorable reservoir sites on smaller tributaries (French Creek, Tionesta Creek, Red Bank Creek, Mahoning Creek, Crooked Creek, and Loyalhanna Creek), but the total storage of these reservoirs is much less than is desirable for the general plan.

Monongahela River.—A favorable reservoir site exists on one smaller tributary (West Fork), but its total storage is much less than is desirable for the general plan.

In 1929 and 1930, the Consulting Engineers of the Flood Commission of Pittsburgh, Ross M. Riegel and H. A. Thomas, Members, Am. Soc. C. E., reviewed the 1928 report of the United States Engineers, and commended the excellence of the engineering surveys, designs, and cost estimates described therein. They called attention, however, to the fact that a reservoir system similar to that described in the report, but of reduced capacity, could be built at a cost of about $58 000 000 (that is, at about 60% of the cost of the eleven-reservoir system), and would be capable of eliminating 87% of the flood damage. They concluded that the expenditure of an additional $38 000 000 to eliminate the last 13% of flood damage would be an uneconomic investment. The concurrence of the United States Engineers in this general conclusion is indicated by the selections made in 1936 of reservoirs for construction under Federal appropriations.

Messrs. Riegel and Thomas showed that the uneconomically high storage capacity and cost of the eleven-reservoir system can best be reduced by eliminating certain of the reservoirs, or by constructing smaller reservoirs at points farther up stream. In general, it is not desirable to decrease the heights of the dams, since this would change the nature of the storage from superior to inferior. It is generally agreed that the first step toward cheapening the system should be the elimination of the proposed large reservoir on the Youghiogheny. Although this reservoir would be of great value for the protection of the Pittsburgh District, its cost is saddled with an enormously expensive railroad relocation.

The reservoir on the Tygart River is now (1937) under construction, and it appears certain that some of the other reservoirs will be built in the near future. The decision as to which are to be started first is yet to be made. The Flood Control Act of 1936 provides that the Federal Government shall carry the construction costs of the authorized projects, while local interests must provide without cost to the United States all lands, easements, and rights of way (within certain limits) necessary for the construction of the project. Legislation providing for the payment of that portion of the cost assessed to the local interests has been enacted by the Legislature of Pennsylvania.

PYMATUNING RESERVOIR

Experience with the recently completed Pymatuning Dam demonstrates the effectiveness of the reservoir method of flood control under conditions encountered on the rivers of Western Pennsylvania. This dam was constructed by the Commonwealth of Pennsylvania to provide an adequate supply of water for manufacturing and domestic use during periods of low discharge on the Shenango River. It is located 86 miles north of Pittsburgh and controls a drainage area of 160 sq miles. The capacity of the reservoir is 8 400 000 000 cu ft and its total cost was $3 750 000.

The first year's operation of the Pymatuning Dam has proved its effectiveness in improving dry-weather flow and in controlling floods. The industrial city of Sharon, Pa., is located 25 miles below the dam, at a point where the drainage area is 640 sq miles. On July 1, 1935, the discharge of the Shenango River at Sharon dropped to 9 cu ft per sec. Although the Pymatuning

Reservoir was only partly filled at this time, the gates were opened and sufficient flow was released to supply the water needed for industrial and domestic purposes in Sharon, Newcastle, and other manufacturing communities. This action prevented the complete shut-down of many important industries from July 1 to December 1, 1935.

Since its completion the Pymatuning Dam has prevented two floods. Shortly prior to January 26, 1937, the level of Pymatuning Lake was 2 ft below the spillway. About that time the occurrence of warm weather and rainfall produced floods on all the rivers of the region, the stage at Pittsburgh, for example, being 34.2 ft on January 26. On this day the level of Pymatuning Lake rose to 0.86 ft over the spillway. Because of this storage of peak run-off, the maximum flood stage at Sharon on January 26 was only 0.36 ft.

When the great storm preceeding March 18, 1936, swept over the Middle States and New England, the Pymatuning Reservoir was not full. The gates were closed and impounded the flow so that no flood damage occurred in the Shenango Valley, and no industries were shut down on account of high water. This was the only river valley in Pennsylvania which did not suffer damage during this flood period. Even at Newcastle, 21 miles below Sharon, where the drainage area is 804 sq miles, there were no serious flood losses.

The owners of important industries in the Shenango Valley claim that the Pymatuning Dam project paid for itself during the first year of its life. In general design and construction this dam is similar to those proposed for flood-control on the Allegheny and Monongahela Rivers.

THEORETICAL CONSIDERATIONS

No reference has thus far been made to the exact effect the various proposed reservoir systems would have on a particular flood. The 1912 report of the Pittsburgh Flood Commission and the 1928 report of the United States Engineers both contain the results of extensive computations purporting to answer such questions. However, a close study of the different methods used in these two computations indicates that in neither case is it possible to have confidence that the final results are accurate. The fact is that, in the present state of the science of hydraulics, no accurate, reliable, and practical analytical method exists for determining the manner in which flood waves from several tributaries will combine to form a single flood wave on a main river.

From considerations based on the volumes under the hydrographs of the tributary floods, together with approximate estimates of the velocity of crest movements, it is possible to form a rough idea of how the tributary waves combine into a single main wave. This was essentially the method used in the 1912 study of the Flood Commission and was the best or only method known to the Engineering Profession at that time. It is, however, subject to errors of large or uncertain magnitude.

In more recent years, a method of flood-wave routing, usually known as the Watkins method, was developed in studies on the Tennessee River under

Colonel L. H. Watkins[25]. This method was used by the United States Engineers in their 1928 studies for flood protection of the Pittsburgh District. It assumes the river to be divided into several reaches extending between successive gaging stations, and the flood period to be divided into several intervals, each ordinarily of 24-hr duration. Each reach during each interval is made to satisfy certain requirements of inflow, outflow, and storage. It has been shown by one of the writers[26] that the errors and uncertainties of this method, as it is ordinarily applied, are probably as great as or greater than those of the simpler approximate method used in the 1912 report of the Flood Commission.

Since little has been published regarding the fundamental hydraulic principles of flood-wave routing, and since a knowledge of these principles is of vital importance in a study of flood protection by reservoirs on a river system the main streams of which are several hundred miles long, it is appropriate to include a brief discussion of the theory at this point. At any cross-section of a river, let z = the elevation of the water surface above datum; v = the mean velocity of the water; t = the time; g = the acceleration of gravity; x = the horizontal distance from the source of the river or from some arbitrary origin; d = the mean depth of the water (cross-sectional area divided by surface width); and s = the hydraulic slope, or loss of head per foot of travel.

The ordinary law that the hydraulic slope of an open channel varies as the square of the velocity is then expressed by the formula, $s = k\,v^2$, in which k is the "conveyance factor" of the channel, involving the effect of both the hydraulic radius and the surface roughness. At any given cross-section, k is a function of z. In general, v and z are functions of both x and t.

In the previously mentioned *Bulletin*[26] it is shown that at any cross-section of a river, the flow must satisfy two conditions: (1) The law of conservation of energy; and (2) the law of continuity or conservation of matter. The differential equations expressing these two laws, respectively, are as follows:

$$\frac{\partial z}{\partial x} + \frac{v}{g}\,\frac{\partial v}{\partial x} + \frac{1}{g}\,\frac{\partial v}{\partial t} + k\,v^2 = 0 \text{ ....} (1)$$

and,

$$d\,\frac{\partial v}{\partial x} + v\,\frac{\partial z}{\partial x} + \frac{\partial z}{\partial t} = 0 \text{ ....} (2)$$

In Equation (1) the names of the terms, in order, are: The "surface slope term", "velocity head term", "acceleration head term", and "hydraulic friction term." In Equation (2) the names of the terms, in order, are, the "prism storage term", the "wedge storage term", and the "rate of rise term."

The derivation of the Equations (1) and (2), being based on fundamental mechanics, is rigidly exact, but the actual integration to obtain numerical solutions of practical problems is by far too intricate and laborious to be workable. To obtain a solution that is workable from the standpoint of human patience and endurance, it is necessary to replace the infinitesimals, ∂x, by finite reaches of the river expressed in miles, and the infinitesimals, ∂t, by finite time intervals expressed in hours. Further, the necessity of labor saving requires that these finite space and time intervals must be made very coarse.

---

[25] H. R. Doc. 185, 70th Cong., 1st Session, Appendix B, Pt. II, pp. 40–52.

[26] "The Hydraulics of Flood Movements in Rivers", by H. A. Thomas, M. Am. Soc. C. E., *Engineering Bulletin*, Carnegie Inst. of Technology, Pittsburgh, 1934.

Unfortunately, this coarseness utterly destroys the accuracy and reliability of the computations. Moreover, to keep the intricacy of the computations within the resolving power of an ordinary human mind, it has been the practice to neglect some of the terms of the fundamental differential equations. For example, the "Watkins method" neglects the second and third terms of Equation (1) and the second term of Equation (2). The fact that the neglected terms may be of great actual importance adds to the fundamental unreliability of these ordinary analytical methods of flood-wave routing. In the writers' opinion, the results of long and tedious computations by these methods are apt to be less accurate and reliable than the results of approximate estimates based on simple assumptions of the type used in the 1912 report of the Flood Commission.

The successful use of mechanical integration in other fields of scientific or engineering practice suggests that it might be possible to construct some integrating machine which would solve the fundamental differential equations of flood motion by a mechanical process. At the Carnegie Institute of Technology, much study has been devoted to the design and operation of devices suitable for this purpose. The most successful machine has been a model channel, of length suitable for indoor construction and with a greatly exaggerated vertical scale, so that depths of flow can be read with the necessary precision. The term, "integrating model", is used to designate a device of this type. Curves of the river are not represented in such a model, the effects of curve friction being taken care of in the roughness adjustment. The construction of each cross-section of the channel of an integrating model to duplicate the area-elevation curve at the corresponding section of the prototype offers only mechanical difficulties. The principal new technical feature involved in the construction of integrating models is the reproduction of the hydraulic friction effect as represented by k.

In the models thus far constructed, the hydraulic friction effect has been produced by sheet-metal baffles extending into the channel from the bed and sides. A technique has been developed for designing these baffles so as to make k vary with z in the model channel in any desired manner[27]. By this process the rating curves of the river can be reproduced in the integrating model, thereby satisfying all the requirements to make the model reproduce the flood-wave hydrographs of the prototype with perfect fidelity.

In such a model of a river system, each important tributary has its own cam-controlled inlet, by which the hydrographs of the tributary floods are reproduced. Several preliminary models representing parts of river systems and involving these principles have been built and tested at Carnegie Institute of Technology, and in 1936, the Pittsburgh Office of the Corps of Engineers recommended construction of a large integrating model of the entire Allegheny-Monongahela River System. At present, work on the construction of this model is under way.

---

[27] "Model Studies of Flood Wave Movement in the Rivers of the Upper Ohio Watershed", by John W. Hackney, Thesis submitted in partial fulfillment of the requirements for the degree of Master of Science, Carnegie Inst. of Technology, 1935.

This model will provide an accurate and reliable method of determining how much various flood crests will be lowered by the retarding reservoir system. It will also be used for flood-forecasting. Provided a sufficient number of automatic recording gages are established in the field, and properly manned, this will make possible early and accurate forecasts of high river stages.

AN IDEAL ORGANIZATION FOR THE RIVER AND FLOOD SERVICE OF THE UNITED STATES WEATHER BUREAU

BY MONTROSE W. HAYES,[28] ESQ.

SYNOPSIS

Flood forecasts may be based on river-gage relations, or on rainfall data, or on both. The demand for flood forecasts has grown rapidly, and the standard of refinement insisted upon, is constantly increasing. This makes necessary the establishment of additional observation stations and the development of more precise methods of prediction. A plan for improving the river and flood service of the United States Weather Bureau is presented.

Flood forecasting on a systematic basis seems to have had its beginning in France in 1854. The extent of the network of stations used is not known, nor is it clear, from the literature available to the writer, what degree of success was attained in making the predictions. However, the obstacles that undoubtedly were in the way were overcome, for the flood-forecasting service in France has not been interrupted since that beginning. Similar work was undertaken in Italy and Bohemia about 1866, and in the United States in 1871, the latter date being one year after the establishment of the National Weather Service.

At present, two distinctly different methods are used by the Weather Bureau in forecasting flood stages. The older and more refined method is based on gage relations and, more recently, on discharge data. The latter method utilizes largely, or altogether, reports of rain that has fallen or is expected to fall.

In forecasting from gage relations and discharge data, intervening rains must be given weight, but the underlying factors are up-river stages. It may seem unnecessary to state that the farther a reach is from its source water, the greater the time range that is possible in making a flood forecast, but the statement is made to bring out more forcefully the difference in the two general methods of forecasting. On the larger streams, or on the reach of any stream several days removed from the regions of the flood-producing rains, there is sufficient time to make the final forecast in refined terms, both as to stage and as to time. This is done now in a satisfactory manner and has been done for as long as 64 yr. The term of the forecasts ranges from 2 or 3 days in the upper valleys to as many as 3 or 4 weeks in the Lower Mississippi basin.

As a rule, it is impracticable to use gage relation or discharge data in making flood forecasts for regions into which flow numerous small streams, that may be considered source-water streams. The gaging of these numerous streams, and of the channels that are water carriers only during heavy rains, is not economically practicable. In general, moreover, the results would be of little value in forecasting. Therefore, it becomes necessary to rely upon reports from rain-gage stations, distributed over the catchment basins in such a way as to provide adequate information on the amount and intensity of the rain, and its geographic distribution. In much of the country east of the Appalachian Mountains, flood forecasts to be timely enough to be of real benefit must be made from rainfall reports.

---

[28] Chf., River and Flood Div., U. S. Weather Bureau, Washington, D. C. Mr. Hayes died November 16, 1936.

The time when the work of the Weather Bureau was principally of academic interest has long since passed, and for many years the field offices, as well as the Central Office, in Washington, D. C., have had difficulty in meeting the calls made on them for general weather information. At offices situated on rivers the demands for river stage and flood forecasts have grown concurrently with the requirements for other service, and as the use of rivers increases these demands will continue to grow. The development of streams for power, navigation, and irrigation, the larger consumptive use of water by growing cities, and the greater use of the flood-plains by industry, all make flood forecasts not only desirable but absolutely necessary. Too, contrary to popular opinion, the successful operation of flood-control works, as well as their construction, requires forecasts of ice-forming weather, of impending rains, and of floods.

The standard of refinement of flood forecasts is set by those who use them. This statement may cause some surprise, but its truth can easily be demonstrated. If the interests along a river can be protected by 2-day forecasts verified in stage with an accuracy of about 2 ft, it would be useless to spend the money necessary to provide 3-day forecasts with an order of accuracy of less than 0.5 ft. On the other hand if the latter and more accurate forecasts were needed, an effort would be made to obtain the money that would make them possible. Because of the unprecedented heights of the floods of March, 1936, when, in inundated cities, each 6 in. of rise meant an additional loss of enormous extent, the Weather Bureau now finds itself facing unprecedentedly widespread demands for river stage and flood forecasts of longer range and greater refinement. In providing them many obstacles will have to be overcome. Changes in the present plan of operation will be necessary, and some outstanding deficiencies must be met. The simpler requirements need not be reviewed here. Others, more complex or difficult of attainment, are presented to show why the Bureau can not immediately strengthen its river service to the extent known to be desirable. These requirements are as follows:

(*a*) The establishment of more and better placed rainfall stations, especially in head-water regions.

(*b*) The installation of an adequate network of recording rain-gages to enable the forecaster to know the intensity of the rainfall. At present, most of the rain-gages used in flood work are of the eye-reading, 8-in. type.

(*c*) Surveys of the amount and condition of snow in the eastern mountains. Few data of this kind are available at present. Reliable and prompt rainfall reports are not sufficient when the mountain regions hold a great quantity of water in the form of snow, which is likely to be released by the rain.

(*d*) Arrangements for a more reliable transmission of rainfall and river-stage reports from the sub-stations to the district centers. In the eastern floods of March, 1936, the failure of wire communication was almost entirely responsible for any lack of timeliness and accuracy in the warnings issued. Except in very unusual cases the telephone and telegraph wires answer all purposes with a great degree of satisfaction, but it is in the unusual cases—the emergencies—that the greatest need for the reports exists. A river forecaster without information from the drainage area above him is helpless. The problem is difficult to solve. It has been suggested that radio stations should be established in flood-producing regions that are without reliable wire communication, and that they should be manned by Weather Bureau employees to transmit reports promptly under all conditions, to the forecasting center. This, of course, would be a solution, but it is believed that the cost would not be justifiable; certainly, it would not be, until it could be shown definitely that the Weather Bureau had exhausted every other and less costly means for having reports transmitted satisfactorily. One plan now (1937) being investigated would utilize amateur radio operators to transmit reports in times of emergency. Another proposal is to find hydrologically satisfactory locations for rain-gages, and for some river gages, from which reports can be sent by automobile to telegraph or telephone offices. This latter procedure would be expensive, but considerably less expensive than the maintenance of Weather Bureau radio stations.

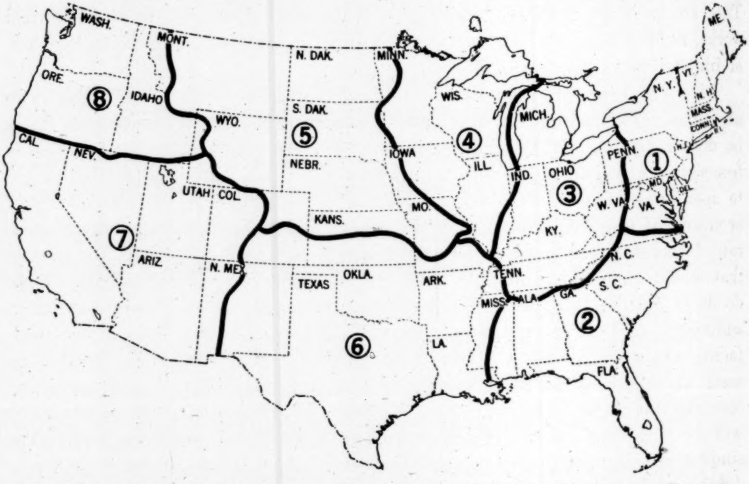

FIG. 17.—PROPOSED DIVISION OF THE UNITED STATES FOR FLOOD-FORECASTING SERVICE.

(*e*) Division of the country into eight sections for river administrative and forecasting purposes (Fig. 17), and the establishment of a staff of men in each section, under a section head, to handle the river work. These men should be charged with: (1) Placing and supervising the operation of the sub-stations; (2) developing and putting into effect a plan for transmitting reports to the forecasting centers; (3) co-ordinating all phases of the work, and co-operating with other organizations engaged in river work; (4) investigating the requirements for forecasts and arranging to meet those requirements; and (5) developing formulas for forecasting. Through a close co-operation with the U. S. Geological Survey, the Weather Bureau is now obtaining discharge data on most of the rivers of the country. This information can be used to advantage, in combination with the data supplied by the Weather Bureau itself, in developing more accurate formulas for river-stage and flood forecasts. However, the officials in charge of the Weather Bureau stations, who have multitudinous duties to perform, have not the time to devote to all the intricacies of the river work. It is obviously necessary to have a number of well-qualified men who can give all their time to studying these data and developing forecasting formulas.

The foregoing list of requirements for a river-forecasting service of a high order of accuracy is not merely something to be desired and never attained. On the contrary, it represents a plan set up by the Chief of the Weather Bureau in 1935. A modest beginning toward its accomplishment was made on July 1, 1936. Small staffs have been placed both in the Missouri Valley and in the Upper Mississippi Valley, and other parts of the country will be taken care of, as it becomes possible to do so.

At present, no definite decision has been reached as to who shall actually make the forecasts. There are sixty-four forecasting centers, and it is thought the usual station personnel can handle the forecasting with the facilities that will be provided by the river and flood staffs. The staffs, however, will be mobile, and in emergencies they will be available to do anything that will aid in issuing timely and accurate warnings of impending floods.

FEDERAL PLANS FOR FLOOD CONTROL

By W. E. R. Covell,[29] M. Am. Soc. C. E.

Synopsis

It was natural that the watercourses and their valleys should have had a great influence in the early settlement, trade, and transportation of the United States since they were the lines of least resistance to the vast unexplored inland country. Later, devastating floods occurred in the valleys and protective measures were sought. The first flood protection sponsored by the Federal Government was in the Mississippi Valley followed by protection in the Sacramento Valley, California. In 1925, Federal interest in river planning of broad scope was manifested, which later resulted in the "308" reports of the Corps of Engineers, U. S. Army, covering the possibilities of navigation, flood control, water power, and irrigation. By June 30, 1935, nine Federal flood-control projects were in force which were followed by twenty-seven additional projects throughout the country to June 22, 1936, when the general Flood Control Act was approved. A Federal policy was thereby established, 219 main flood-control items were authorized in 46 major basins and localities, and 232 localities were designated for further investigation. Fourteen reservoirs were authorized for the protection of Pittsburgh, Pa., and the Ohio Valley, based upon the "308" reports. The general features of the reservoir system, which contemplates control of flood waters at or near their source, are presented.

Introduction

It was natural that the watercourses should have had a great influence in the early settlement, trade, and transportation of the United States. They were the lines of least resistance to the vast unexplored country that lay inland; they provided transportation for the settlers and power for the first mills; and their fertile valleys produced rich crops and afforded topographically favorable town sites.

They were not an unmixed blessing, however. When the valleys were first settled, they were accepted in the condition in which they were found, because the country was new. Later, devastating floods were experienced, which went their way to the sea in the channels which Nature had provided. When the primary banks could not confine the flows they spread to the flood-plains of the inhabited valleys.

Man's ingenuity was aroused, and he sought to protect himself and his property. The progressive development of the valleys was accepted as a necessity and protective measures were early devised to keep the flood-waters within bounds. To-day such work is still in progress. The extreme floods of recent times and the heavy losses sustained thereby have aroused the country at large as never before to a realization of their effect upon welfare and progress. In the last analysis, economic justification will probably govern the extent to which flood protection will eventually be provided.

Flood Control on the Mississippi River

The largest drainage basin of the country is that of the Mississippi River, with an area of 1 240 000 sq miles. The total area of the Continental United States is 3 026 789 sq miles. This basin includes all or parts of thirty-one States and about 20 000 sq miles of Canada. The first levee along the Mississippi River was built by the French in about 1718. Levees were gradually extended with the growth of settlements, under provisions of the land grants, which required the grantee to construct and maintain a levee line along the river front of his property.

The floods of 1849 and 1850 caused widespread damage in spite of the levees. National interest was aroused by the pleas for Federal aid and resulted in the Swamp Land Act of 1850, which granted to the several States all unsold swamp and overflowed lands within their limits to provide funds to reclaim the districts subject to overflow. In 1850, also, Congress authorized a topographical and hydrographic survey of the delta of the Mississippi River, with such investigation as might lead to the determination of the most practical plan for securing it from inundation. This work was placed in charge of Captain A. A. Humphreys, later assisted by Lieutenant H. L. Abbot, both of the Corps of Topographical Engineers, U. S. Army. Another survey and report of a similar nature, authorized by Congress in the same year, was made by Charles Ellet, a Civil Engineer employed by the Corps of Engineers.

The formation of the Mississippi River Commission was authorized by Congress in 1879. It consisted of seven commissioners of whom three were required to be from the Corps of Engineers, U. S. Army, one from the United States Coast and Geodetic Survey, and three from civil life. Two of the latter must be civil engineers. Between 1890 and 1917, the periodic appropriations made by law for expenditure by the Commission were divided among levees, revetments, and dredging, but the levees were considered as an adjunct to river improvement. It was not until the Flood Control Act of March 1, 1917, that by law, flood control as such became a definite part of the work of the Commission. The Act of 1917 provided for co-operation by local interests which were required to provide the necessary rights of way, pay not less than one-third of the cost of levee construction, and to assume the entire cost of maintenance after completion. The cost of river improvement (revetment and dredging) was to be paid for entirely from Federal funds.

In 1927, the Lower Mississippi River experienced the highest flood of record to that time. More than 200 breaches in the levees occurred, although it is of interest to note that only a few were in levees built by the Commission, and only one in a levee built to the Commission's standard dimensions. Public interest was aroused by the catastrophe, which submerged about 20 000 sq miles of the valley and cost the lives of about 250 persons. The Flood Control Act of 1928 resulted, based on the report of the late Major General Edgar Jadwin, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., then Chief of Engineers. The project for the valley of the Mississippi River, as outlined in this Act, provides for the control of flood waters from Rock Island, Ill., to the Head of Passes near the Gulf of Mexico, by means of levees. Tributaries and outlets, in so far as they are affected by the Mississippi River, are also included within the scope of the project. (The alluvial valley of the Mississippi River consists of the St. Francis, the Yazoo, the Tensas, and the Atchafalaya basins, as well as the alluvial lands around Lake Pontchartrain.) The plan called for raising existing levees by about 3 ft and strengthening them, and permitting flood waters in excess of the safe capacity of the leveed channel to find their way to the Gulf through the natural floodways in the lowlands adjacent to the river, which have always carried the waters of extraordinary floods. Levees were planned on the edges of these natural floodways, to restrain the waters within them as far as practicable and to protect the maximum area of land that it was economically justifiable to reclaim. The flood waters would not escape into the floodways until they reached a dangerous stage in the main leveed channel.

An appropriation of $325 000 000 was authorized by the Act of 1928 for carrying on this work. The Act further provided for local co-operation in the project to the extent that States or levee districts were required to maintain the flood-control works, except the controlling and regulating structures, after their completion; provide all the necessary rights of way without cost to the United States; and contribute 33⅓% of the cost of the project work between Rock Island, Ill., and Cape Girardeau, Mo. A later Act, approved April 23, 1934, provided for the reimbursement of States or local levee districts for the cost of the rights of way or easements required for the levees which the Federal Commission was obligated to provide under the Act of May 15, 1928, provided the cost was reasonable.

The general project for flood control on the Lower Mississippi River adopted by the Act of May 15, 1928, has been amended by the Flood Control Act of June 15, 1936[30], and modified in accordance with the report of February 12, 1935, of the Chief of Engineers, U. S. Army[31]. The adopted modifications of the project consist of the following: (1) The abandonment of the Boeuf Floodway, and in lieu thereof the construction of the Eudora Floodway (west of the Mississippi River, and extending from the latitude of Eudora, Ark., into the Red River back-water area), with a control structure at its head; (2) the construction of a rear protection levee extending from the head of the Eudora Floodway north to the Arkansas River, located so as to afford adequate space for the escape of flood waters without endangering the levees on the east side of the river; (3) the maintenance of the present river levees between the head of the

[31] H. R. Committee on Flood Control, Doc. No. 1, 74th Cong.

Eudora Floodway and the northern junction with the protection levee, at the 1914 grade and section, except in front of densely populated areas, as a part of a ring levee; (4) the construction of a floodway extending from the Mississippi River north of Morganza, La., to the Atchafalaya River back-water, with a control structure at its head; (5) the raising of the levees from the head of this floodway to the head of the Atchafalaya River to full standard grade and section; (6) the immediate completion of the guide levees in the Atchafalaya basin to afford full protection to all lands outside of these levees; (7) the construction of an additional outlet to the Gulf of Mexico, west of Berwick, La.; (8) the increase of the discharge capacity of the leveed channel of the Atchafalaya River and of its outlets; (9) a six-year program for the improvement and regularization of the Mississippi River, including the continued maintenance of the navigation channel provided in the previous project; and (10) the flood control of the St. Francis and Yazoo Rivers.

It was contemplated that the unfinished parts of the levees and structures authorized by the Act of 1928 and not modified by the Act of May 15, 1936, would be completed as planned. The total estimated cost of all works added to the previous project, including the acquisition or reimbursement for land rights, was $313 000 000, or $245 000 000 in excess of the unappropriated balance of the appropriation previously authorized.

Federal Interest in Other Streams

The first expansion of Federal interest in flood control to another locality of the United States was authorized by the Flood Control Act of March 1, 1917. It resulted in a general project for flood control, including channel enlargement, cut-offs, by-pass weirs, outfall gates, and levees, for the Sacramento River, in California. The project, later modified by the Flood Control Act of May 15, 1928, represents the outgrowth of the early activities of the California Débris Commission created by an Act of Congress in 1893, and consisting of three officers of the Corps of Engineers, U. S. Army. The Act of 1917 required that the State of California share equally with the United States in the cost of the works, and in addition, that all rights of way, easements, and lands be provided free of cost to the Federal Government. The Flood Control Act of May 15, 1928, required the State or other local interests to contribute one-half the cost of constructing the levees to Commission standards and to complete the project.

In 1925, Federal interest was manifested in river planning of a broad scope. The River and Harbor Act approved on March 3 of that year directed the Secretary of War and the Federal Power Commission jointly to prepare and submit to Congress an estimate of making such examinations, surveys, or other investigations, as in their opinion were required for those navigable streams of the United States, and their tributaries, whereon power development appeared feasible and practicable, with a view to formulating general plans for the purposes of navigation and for the prosecution of such improvements in combination with the most efficient development of the potential water power, the control of floods, and the needs of irrigation. The streams and their tributaries to be investigated were designated in a Federal report[32], and the River and Harbor Act of January 21, 1927, directed the Chief of Engineers to prosecute the investigations. The resulting reports have become quite generally known as the "308" reports.

The work covered practically all the principal drainage systems of the United States. The surveys first authorized, involved an estimated cost of $7 322 400. In addition, the Flood Control Act of May 15, 1928, authorized the expenditure of $5 000 000 of flood-control funds for surveys of tributaries of the Mississippi River. In particular, the Chief of Engineers was thereby directed to make a comprehensive and detailed investigation of the possible alleviation of Mississippi River flood conditions by means of reservoirs, operated either primarily for that purpose or for some other purpose or combination of purposes, on tributaries of the Mississippi that were included in the "308" list. Further study or review of the "308" reports is authorized by Section 6 of the River and Harbor Act of August 30, 1935. By June 30, 1935, a total of $10 254 123.13 had been allotted. The work was conducted by the Corps of Engineers, through thirty-six of the forty-three District Offices. The resulting reports, together with other reports by the Corps of Engineers, furnished the basis for the flood-control projects adopted by the Flood Control Act of June 22, 1936. In addition to flood control proper, the possible influence of potential water power and irrigation developments on flood control has been covered in the "308" studies.

It is interesting to note the status of Federal flood control in the United States and Territories as of June 30, 1935. Under Federal Public Works and Emergency Relief programs, nine flood control projects were in force, seven of them in various parts of the United States and two in Alaska, in addition to the initial Mississippi and Sacramento River projects. These projects were: Winooski River System, Vermont (reservoir system); Wallkill River System, New York (channel improvement); South Canadian River, New Mexico (reservoir); New River, West Virginia (reservoir); Tygart River, West Virginia (reservoir); Muskingum River System, Ohio (reservoir system and channel improvement); Los Angeles and San Gabriel Rivers, California (flood-control system); Salmon River, Alaska (dikes and clearing); and Lowell Creek, Alaska (dam). The total estimated cost of these projects was more than $100 000 000, including the cost of construction and land and damages. Most of them required local co-operation, principally with respect to the payment for land and damages.

Between June 30, 1935, and the approval of the general Flood Control Act of 1936, a total of twenty-seven additional flood-control projects was approved for construction under provisions of the Emergency Relief Appropriation Acts of 1935 and 1936. These projects were scattered throughout the country and consisted of levee, channel, cut-off, flood-wall, and reservoir improvements at a total estimated cost of about $22 351 000. Payment for lands and damages was the responsibility of local interests. Notable projects in this list were the Sardis Reservoir, in the Yazoo River basin, Mississippi (a part of the modified plan for Mississippi River flood control); and the Possum Kingdom Reservoir, on the Brazos River, Texas (one of the thirteen reservoirs planned by the Brazos River Conservancy and Reclamation District).

---

[32] H. R. Doc. No. 308, 69th Cong., 1st Session.

THE FLOOD CONTROL ACT OF 1936

The Flood Control Act of June 22, 1936, opens a new era for flood control in the United States. For the first time in the history of the nation, a Federal policy with respect to flood control for the country at large is adopted by law. The first four sections and Paragraph 1 of Section 5 of the Act are contained in the Appendix.

Analysis of the provisions of the Flood Control Act discloses the following general features: (*a*) Flood-control projects are authorized in 46 major basins and localities throughout the United States; (*b*) the Act contains 219 main flood-control items, some of which involve several sub-items; (*c*) the types of projects include channel improvements, dikes, reservoirs, levees, cut-offs, diversions, floodways, and flood walls; and (*d*) the estimated total cost of the projects authorized is from $396 532 880 to $397 532 880, of which $300 571 325 is for construction and from $95 961 555 to $96 961 555 is for land and damages. In addition to the authorization of definite flood-control projects, the Act provides for preliminary examinations and surveys for flood control at 222 localities throughout the United States, and for surveys, studies, and reports at 10 Southern and Western localities where there are indications that opportunities may exist for useful flood control in combination with hydro-electric power development whenever sufficient markets become available to absorb the power.

The Act of 1936 does not repeal the Flood Control Act of 1928, or any provision of any law amendatory thereof. The sum of $310 000 000 is authorized to be appropriated for the flood-control projects adopted by the Act. Not more than $50 000 000 may be expended during the fiscal year ending June 30, 1937, and provision is made for relief of unemployment, in constructing the projects.

The Flood Control Act of 1936 represents national stream planning on a large scale. The most meritorious projects of the country at large are included in the initial program of development. The further possibilities are recognized. The ultimate development will likely be determined by economics of cost and benefit.

The Federal policy with respect to local co-operation in projects has been traced in this paper from the original flood-control project on the Mississippi River to the present time. Such co-operation has largely attended the development of flood control and is a feature of the Act of 1936 which provides that when the cost of the land, rights of way, and damages exceeds the construction cost of a project, the resulting participation of the Federal Government and the local interests is on an equal basis. Local interests are required to maintain and operate all the flood-control works after completion.

The project for the Ohio River basin authorized by the Flood Control Act of June 22, 1936, provided for two features, namely:

"Reservoir System for the Protection of Pittsburgh: Construction of reservoirs for the Allegheny-Monongahela basin as in comprehensive plan for the protection of Pittsburgh and for the reduction of flood heights in the Ohio Valley generally, as set forth in House Document Number 306, 74th Congress, 1st Session, and in the report on the Allegheny-Monongahela Rivers and tributaries on record in the Office of the Chief of Engineers; estimated construction cost, $20 646 000; estimated cost of lands and damages, $34 569 000.

"Reservoir System for the Reduction of Ohio River Floods Below Pittsburgh: Construction of reservoirs including the completion of the Bluestone Reservoir now under way, which together with the reservoirs for Pittsburgh flood control, constitutes a comprehensive plan for flood control on the main stream of the Ohio River and on the tributary stream below the reservoirs, as set forth in House Document Number 306, 74th Congress, 1st Session; estimated construction cost, $19 616 800; estimated cost of lands and damages, $10 519 600."

The report mentioned as being on record in the Office of the Chief of Engineers is an unpublished report, and House Document No. 306, 74th Congress, 1st Session, is a published report, both prepared in accordance with House Document No. 308, 69th Congress, 1st Session.

Projects in the Ohio Basin

The Ohio River is formed by the confluence of the Allegheny and Monongahela Rivers at Pittsburgh, Pa., and flows in a general southwesterly direction 981 miles to enter the Mississippi River at Cairo, Ill. The river discharge varies widely, the maximum and minimum at the mouth being 1 600 000 (prior to January, 1937) and 22 000 cu ft per sec, respectively. The basin, which embraces parts of fourteen States, is 800 miles long and has an area of approximately 204 000 sq miles. The topography is greatly diversified. In the northern and western areas the surface is generally flat to rolling, whereas in the eastern and southern areas it is rugged and mountainous. The normal annual precipitation for the basin is 45 in. varying from 83 in. in the southeastern mountainous part to 31 in. in the northwestern part.

Because of its large and extensively developed coal fields, the basin is one of the principal industrial regions of the United States. The outstanding development is that of the iron and steel industry, centered at Pittsburgh, Pa., and extending up the Monongahela River and down the Ohio River. Cincinnati, Ohio, Louisville, Ky., and Wheeling, W. Va., are other large centers of industry on the river. Outside the industrial regions, agriculture and coal mining are the principal activities.

High stages occur frequently on the Ohio River and its tributaries, the range in stage from low water to high water attaining 70 ft (prior to January, 1937) in some reaches of the main river. The bottom-lands, however, are generally narrow, and most of the cities, roads, etc., are above the ordinary flood stages. Nevertheless, between 1876 and 1936 twenty-three floods have risen 5 ft, or more, above ordinary flood stage, with damage to cities, towns, industries, railroads, and highways. A large part of this damage is due to the flooding of basements and the lower floors of buildings, with consequent injury to goods and furniture therein. Crop damages are of less importance. Prior to the flood of March, 1936, the average annual flood loss on the main stem of the river, exclusive of Pittsburgh, was estimated at $1 860 000. (About two-thirds of this loss is at or above Cincinnati, because of the large industrial development along the upper river, and the relatively greater flood heights there experienced.) It was also estimated that an effective system of flood control would afford an annual benefit of about $1 000 000 to the lands bordering the Ohio River, because of increased value for urban or farm use.

Reports have shown that the construction of levees or walls for the protection of towns and cities on the Ohio River against high floods appears to be economically justified in only certain cases. The cost of levees for the protection of agricultural lands would greatly exceed any possible benefits.

Because of the intensive development of the valleys, the construction on the main rivers, of dams of sufficient height to afford flood storage and effective power development would inflict widespread and costly flowage damage. For the control of floods in the Mississippi Valley, the most effective location for such a dam would be near the mouth of the Ohio River, but investigation of the most practicable site, has shown it to be inadvisable. The same is true of other possible sites in the more highly developed upper parts of the Ohio Valley. Flood control on the Ohio River, therefore, must primarily be obtained by works on its tributaries.

A compilation of the most favorable plans for the comprehensive development of the water resources of the Ohio River basin, as developed in the "308" surveys, shows that about 250 water-power developments, supplemented by 32 flood-control reservoirs, and levees and channel improvements on tributaries, may eventually be warranted. The total installed hydro-electric capacity of such a comprehensive system would reach 8 600 000 kw. So large an amount of power could not be absorbed for many years, and, obviously, such a development could only be made progressively, as the growth of the power market justified the individual installations. The total cost of such a comprehensive development is estimated in the "308" reports at $1 700 000 000, and the annual charges at $160 000 000. The possible future annual returns from power are estimated at $169 000 000; the annual benefits from flood control (largely on the tributaries), at $8 600 000; and the annual benefits to water supply and navigation, at $500 000.

A possible comprehensive reservoir plan for the alleviation of floods on the Mississippi River, through works designed for the control of floods on its tributaries was investigated in connection with the "308" reports. It included 81 reservoirs on the tributaries of the Ohio, with a capacity of 25 300 000 acre-ft. The estimated cost of these 81 reservoirs was $517 000 000.

Three large flood-control reservoir projects included in the comprehensive plan are now (1937) under construction in the basin. One of these, on the Tygart River, a tributary of the Monongahela River, is not only for the purpose of flood control but also to assure an adequate supply of water for the operation of the locks on the Monongahela during periods of extreme drought, such as occurred in 1930. The dam is being built by the War Department with funds allotted by the Public Works Administration. The second project is a system of reservoirs for the control of floods on the Muskingum River and its tributaries, which has been undertaken by the War Department in co-operation with the Muskingum Conservancy District. This project fulfills the purpose of two of the reservoirs contained in the comprehensive plan. The third project is the Norris Dam, on Cove Creek, a tributary of the Tennessee River, nearing completion by the Tennessee Valley Authority.

The Chief of Engineers in 1935 approved the selection of fourteen additional flood-control reservoirs in the Ohio Basin, the immediate construction of which appeared to be warranted. They will be built by the Federal Government after appropriation of funds, provided local interests furnish the necessary lands and flowage, hold and save the United States against damage, and take over the works after completion. These works include nine reservoirs above Pittsburgh, forming the comprehensive plan for the protection of that city, three on the tributaries of the Kanawha, and two on the Licking River, which enters the Ohio opposite Cincinnati. The total estimated cost of the nine dams above Pittsburgh was $55 215 000, of which $20 646 000 was for construction and $34 569 000 was for lands and damages. At one of the project reservoirs on the tributaries of the Kanawha (the Bluestone Reservoir on the New River), power production can apparently be combined with flood control. The construction of this reservoir and appurtenant power installation at an estimated cost of $13 000 000 was recommended in a comprehensive report on the Kanawha River[33], provided a definite agreement could be entered into for the disposal of the power at prices that would protect the public interest. The total cost of the other two flood control reservoirs on the Kanawha was estimated at $9 849 000 of which $2 886 000 was for construction and $6 963 000 was for lands and damages. The total cost of the two proposed reservoirs on Licking River was estimated at $7 345 000, of which $5 046 000 was for construction and $2 299 000 was for lands and damages. The total estimated cost of the construction of the reservoirs recommended, exclusive of the Bluestone Reservoir, was $28 578 000, and the total estimated cost of lands and damages was $43 831 000. The estimates were made at the time the "308" reports were prepared.

The system of fourteen reservoirs, together with the reservoirs now under construction on the Tygart and Muskingum Rivers, may be expected to reduce the peak of a great Ohio River flood, similar to that of 1913, by 7.5 ft at Pittsburgh, 3 ft at Cincinnati, 1.6 ft at Louisville, and about 6 in. at Cairo. Lesser floods, in general, would be reduced to a greater degree. The direct annual benefits from this system of reservoirs were estimated (prior to the great floods of March, 1936, and January, 1937) at $4 100 000, and the annual carrying charges at $3 416 000. The flood of March, 1936, is the highest of record in the Upper Ohio River and resulted in new data as to the probable frequencies of high stages. These data indicate that the flood-control benefits will be greater than previously estimated. The drainage area to be controlled by the system of fourteen reservoirs is 15 936 sq miles of the 204 000 sq miles total for the Ohio River basin. The gross capacity of the reservoirs amounts to 3 169 510 acre-ft.

---

[33] H. R. Doc. No. 91, 74th Cong. 1st Session.

The immediate local effect and benefit of a flood-control reservoir is directly tangible and certain, but its effect on flood heights at the more remote localities on the main stem of the Ohio River is less certain. The just apportionment of the cost of structures of this character between the Federal Government and the local interests presents a considerable problem. The apportionment under which the construction cost would be borne by the United States and the land damages by local interests is considered advantageous, in that it assigns to local interests that part of the cost which they can most effectively undertake.

Prior to 1936, great floods had been experienced at Pittsburgh, notably in 1762, 1763 (the succeeding year), 1809, 1810 (another succeeding year), 1816, 1832, 1884, 1902, and 1907. The flood menace has ever been present, but the risk has been accepted and the flood losses taken as they occurred. In March, 1936, the Pittsburgh area experienced its greatest flood of record; the river reached a stage of 46 ft which was 21 ft above flood stage, 7½ ft higher than the great flood of March 7, 1907, and 12.6 ft higher than that of March, 1913, which was an extremely high flood for the Ohio River as a whole. It had been predicted as the result of engineering studies by the Flood Commission of Pittsburgh published in 1912, that Pittsburgh would some day experience a 43-ft flood. The flood studies of the War Department indicated that a 47-ft flood stage was possible under certain conditions. From 1854, when continuous records began, to the close of 1936, 93 flood stages, or an average of 1.1 per yr, have occurred at Pittsburgh. According to the all-time record dating back to January 9, 1762, the eleven highest floods crested at stages ranging from 35 to 46 ft. The month of March is the most prolific for occurrence of floods at Pittsburgh; January ranks second, February third, and December fourth.

With the benefit of the continuous record of floods over a long period of time, floods of various heights may be given a frequency rating according to the law of probability The flood of March, 1936 (46 ft), may be expected to occur once about every 270 yr, and the flood of March, 1907 (38.5 ft), once about every 26 yr. At first thought, these frequencies appear to lend some comfort to unfortunates situated in the stricken areas. Although it is entirely possible that this generation may never witness a recurrence of the March, 1936, flood, the menace is ever present and high waters may occur close together. This possibility was borne out in 1762 and 1763, when stages of 39 and 40.9 ft, respectively, occurred at Pittsburgh.

The Pittsburgh area lies within the influence of both the Allegheny and Monongahela River Systems, the flood waters of which converge to the head of the Ohio River. The time of arrival of the flood crests from these river systems, at Pittsburgh, has an important bearing upon the height of the flood stages, which is also influenced by the peculiarities of the distribution of precipitation over the separate drainage areas. The differences in latitude and altitude and related temperatures over the basin are ordinarily redeeming factors, although under some circumstances these factors may become completely nullified. The respective natural peculiarities of the adjoining Allegheny and Monongahela River basins have been instrumental in minimizing the number of floods experienced at Pittsburgh. However, there is always the possibility that conditions may be such that the converging flood waters from the two basins may arrive at Pittsburgh at nearly or at exactly the same time, with disastrous results.

The possibility of flood control by means of reservoirs in the Allegheny-Monongahela basin has been the subject of numerous investigations beginning with that of the Flood Commission of Pittsburgh. The principal object of these flood-control investigations has invariably been to determine the feasibility of the control of floods at or near their source, since it is readily recognized that such control would be productive of the most widespread benefits. In effect, a part of the drainage area would be practically cut off from the remainder by means of flood detention reservoirs. Such reservoirs should have sufficient capacity to retain practically the entire inflow thereto until it can be released so as to reach Pittsburgh after the high water from the intermediate, uncontrolled drainage area above that city has gone on down the Ohio River. As the Monongahela and Lower Allegheny River Valleys cannot advantageously be utilized for reservoirs, resort must be had to locations on the head-waters and the principal tributaries. The individual reservoir sites that have been considered in the investigations have been selected after a study of the physical and economic features of the basin as a whole although, in this respect, the basin offers little choice of sites, and with a view to distributing the individual units so that as many of them as possible would become effective no matter what the particular storm and consequent run-off conditions might be.

As a result of previously mentioned investigations and reports by the U. S. Corps of Engineers, the Tygart River Reservoir was authorized and is now (1937) under construction at an estimated cost of $15 700 000. This reservoir will have a capacity of 314 000 acre-ft for the control of spring floods, equivalent to a run-off of 5 in. of rainfall from the tributary area of 1 183 sq miles. The reservoir is also designed to provide an adequate low-water discharge for navigation purposes on the Monongahela River. As a flood-control reservoir, it will serve as the initial unit in any flood-control reservoir system which may be provided in the Allegheny-Monongahela River basin.

The project system of flood-control reservoirs for the Allegheny-Monongahela River basin above Pittsburgh adopted by the Flood Control Act approved June 22, 1936, consists of nine units, in addition to the Tygart Reservoir. This system may be considered tentative. Revision of the "308" studies by bringing them up to date may indicate that additional reservoirs or other facilities may be economically justified. The total capacity of the project system, including the Tygart Reservoir, would be 2 272 500 acre-ft and the total amount of the drainage area controlled would be 7 487 sq miles. The basin above Pittsburgh comprises 19 117 sq miles, which would leave 11 630 sq miles, or 61% of the basin, uncontrolled by reservoirs.

Investigation of the probable effectiveness of the reservoir system indicates that the flood of March, 1907 (stage, 38.5 ft at Pittsburgh), would have been reduced to a stage of 31.5 ft and the flood of January, 1913 (stage, 34.3 ft) to 27.9 ft. For the great flood of March, 1936 (stage, 46 ft), studies indicate that the reduction in stage would have been about 7.7 ft. Slightly reduced benefits resulting from the reservoir system would also extend down the Ohio River to and below Wheeling, W. Va.

The total cost of the nine reservoirs of the system was estimated at the time the "308" reports were made, to be $55 215 000, of which $20 646 000 would be for construction and $34 569 000 for land and damages. It is evident that the Allegheny-Monongahela River basin does not represent virgin territory in which reservoirs may be built cheaply at favorable physical locations. Railroad lines early pre-empted the main valleys in a region of extensive natural resources. In every reservoir site, except one (Crooked Creek), existing rail development would be affected, and in some cases extensive relocation would be required. Numerous small villages would also have to be abandoned.

The benefits that would result from flood control by means of reservoirs should outweigh the cost of providing the facilities. Although a flood of the magnitude of March, 1936, causes widespread damage of very great amount, it is of infrequent occurrence, so that the average annual damage from such floods is relatively small. The floods of small heights, although they have a high frequency, also result in relatively small annual damages. It is the floods of intermediate height; that is, neither extremely high nor just barely flood stage, that result in the greatest amount of average annual damages, since the damage per flood is relatively high and they occur fairly often.

The unprecedented flood of March, 1936, in the Upper Ohio River area presented some new evidence of cause and effect of extreme floods. The project reservoir system, however, was planned to accommodate certain hypothetical floods. These represent the probable results of the translation of large storms of record, such as that of March, 1913, which involved only a part of the Upper Ohio River basin, to more effective positions on the basins. Some adjustment of the reservoir system may be found desirable in view of the March, 1936, flood. This matter is now (1937) under investigation as provided for under the various Acts of Congress. The City of Johnstown, Pa., (in the Allegheny River basin) experienced a devastating flood in March, 1936. Flood-control measures for that area are also under consideration. A reservoir, or reservoir system, above Johnstown would supplement the reservoir system for the protection of Pittsburgh and the Ohio Valley. The existing reservoir system project, however, would have to be modified by Congressional action to include such facilities.

The flood-control work of the Corps of Engineers, U. S. Army, has been and will continue to be prosecuted in obeisance to the mandates of Congress. Flood control is essentially a matter of engineering and economics, and it is recognized that it presents many problems which must be solved effectively, perhaps boldly, and economically. The endeavor has been made to formulate projects which are comprehensive, co-ordinated, practical and economic. Revisions and additions may be required to a certain extent. A high standard of engineering is imperative in dealing with flood problems lest failure of works designed to withhold floods result in greater catastrophes than the floods themselves. In the investigation and design of flood-control structures the Corps of Engineers has upon occasion retained many eminent engineers from civil life, as well as eminent geologists, in a consulting capacity. After all the years since the early settlement of the United States, it appears that at last flood control has attained a proper place among the numerous activities of the Federal Government, for the welfare of the country. However, States, political subdivisions thereof, and other responsible local agencies must also do their part.

APPENDIX

ABSTRACT OF THE FLOOD CONTROL ACT[34] APPROVED JUNE 22, 1936

AN ACT

Authorizing the Construction of Certain Public Works on Rivers and Harbors for Flood Control, and for Other Purposes.

Be It Enacted by the Senate and House of Representatives of the United States of America in Congress Assembled,

DECLARATION OF POLICY

Section 1. It is hereby recognized that destructive floods upon the rivers of the United States, upsetting orderly processes and causing loss of life and property, including the erosion of lands, and impairing and obstructing navigation, highways, railroads, and other channels of commerce between the States, constitute a menace to national welfare; that it is the sense of Congress that flood control on navigable waters or their tributaries is a proper activity of the Federal Government in cooperation with States, their political subdivisions, and localities thereof; that investigations and improvements of rivers and other waterways, including watersheds thereof, for flood-control purposes are in the interest of the general welfare; that the Federal Government should improve or participate in the improvement of navigable waters or their tributaries, including watersheds thereof, for flood-control purposes if the benefits to whomsoever they may accrue are in excess of the estimated costs, and if the lives and social security of people are otherwise adversely affected.

---

[34] Public Doc. No. 738, 74th Cong., H. R. 8455.

Section 2. That, hereafter, Federal investigations and improvements of rivers and other waterways for flood control and allied purposes shall be under the jurisdiction of and shall be prosecuted by the War Department under the direction of the Secretary of War and supervision of the Chief of Engineers, and Federal investigations of watersheds and measures for run-off and waterflow retardation and soil erosion prevention on watersheds shall be under the jurisdiction of and shall be prosecuted by the Department of Agriculture under the direction of the Secretary of Agriculture, except as otherwise provided by Act of Congress; and that in their reports upon examinations and surveys, the Secretary of War and the Secretary of Agriculture shall be guided as to flood-control measures by the principles set forth in Section 1 in the determination of the Federal interests involved; Provided, That the foregoing grants of authority shall not interfere with investigations and river improvements incident to reclamation projects that may now be in progress or may be hereafter undertaken by the Bureau of Reclamation of the Interior Department pursuant to any general or specific authorization of law.

Section 3. That hereafter no money appropriated under authority of this Act shall be expended on the construction of any project until States, political subdivisions thereof, or other responsible local agencies have given assurances satisfactory to the Secretary of War that they will (*a*) provide without cost to the United States all lands, easements, and rights-of-way necessary for the construction of the project, except as otherwise provided herein; (*b*) hold and save the United States free from damages due to the construction works; (*c*) maintain and operate all the works after completion in accordance with regulations prescribed by the Secretary of War: Provided, That the construction of any dam authorized herein may be undertaken without delay when the dam site has been acquired and the assurances prescribed herein have been furnished, without awaiting the acquisition of the easements and rights-of-way required for the reservoir area: And provided further, That whenever expenditures for lands, easements, and rights-of-way by States, political subdivisions thereof, or responsible local agencies for any individual project or useful part thereof shall have exceeded the present estimated construction cost therefor, the local agency concerned may be reimbursed one-half of its excess expenditures over said estimated construction cost: And provided further, That when benefits of any project or useful part thereof accrue to lands and property outside of the State in which said project or part thereof is located, the Secretary of War with the consent of the State wherein the same are located may acquire the necessary lands, easements, and rights-of-way for said project or part thereof after he has received from the States, political subdivisions thereof, or responsible local agencies benefited the present estimated cost of said lands, easements, and rights-of-way, less one-half the amount by which the estimated cost of those lands, easements, and rights-of-way exceeds the estimated construction cost corresponding thereto: And provided further, That the Secretary of War shall determine the proportion of the present estimated cost of said lands, easements, and rights-of-way that each State, political subdivision thereof, or responsible local agency should contribute in consideration for the benefits to be received by such agencies: And provided further, That whenever not less than 75 per centum of the benefits as estimated by the Secretary of War of any project or useful part thereof accrue to lands and property outside of the State in which said project or part thereof is located, provision (*c*) of this section shall not apply thereto; nothing herein shall impair or abridge the powers now existing in the Department of War with respect to navigable streams: And provided further, That nothing herein shall be construed to interfere with the completion of any reservoir or flood control work authorized by the Congress and now under way.

Section 4. That consent of Congress is hereby given to any two or more States to enter into compacts or agreements in connection with any project or operation authorized by this Act for flood control or the prevention of damage to life or property by reason of floods upon any stream or streams and their tributaries which lie in two or more such States, for the purpose of providing, in such manner and such proportion as may be agreed upon by such States and approved by the Secretary of War, funds for construction and maintenance, for the payment of damages, and for the purchase of rights-of-way, lands, and easements in connection with such project or operation. No such compact or agreement shall become effective without the further consent or ratification of Congress, except a compact or agreement which provides that all money to be expended pursuant thereto and all work to be performed thereunder shall be expended and performed by the Department of War, with the exception of such reasonable sums as may be reserved by the States entering into the compact or agreement for the purpose of collecting taxes and maintaining the necessary State organizations for carrying out the compact or agreement.

Flood Control Act of 1936

Section 5. That pursuant to the policy outlined in Sections 1 and 3, the following works of improvement, for the benefit of navigation and the control of destructive flood waters and other purposes, are hereby adopted and authorized to be prosecuted, in order of their emergency as may be designated by the President, under the direction of the Secretary of War and supervision of the Chief of Engineers in accordance with the plans in the respective reports and records hereinafter designated: Provided, That penstocks or other similar facilities, adapted to possible future use in the development of adequate electric power may be installed in any dam herein authorized when approved by the Secretary of War upon the recommendation of the Chief of Engineers.

DISCUSSION

Fred C. Scobey,[35] M. Am. Soc. C. E. (by letter).—In the Symposium under discussion reference is made to the use of snow surveys, in forecasting floods. When sufficient snow-survey data have been accumulated for any major water-shed then, of course, excessive snow depth and water content will be indicative of a heavy run-off. This information can be directly applied to streams in which floods are always, or nearly always, dependent on snow melting, such as the Colorado River of the Far West. For streams in which floods are developed by torrential rains alone, or by hard rains on top of snow, such as occur in the Gila River water-shed, of course a snow survey does not apply or merely indicates a contributing factor.

In 1936, snow surveys were extended in the West, by many agencies acting through the U. S. Bureau of Agricultural Engineering as a clearing house, until now they cover nearly all the Western States. The purpose of this information is to forecast run-off by the Bureau of Agricultural Engineering through its Irrigation Division. Primarily, the interest of this agency lies in irrigation and supplemental power, although, of course, the information developed is equally valuable to hydro-electric interests, to those responsible for city water supplies, and to the operators of the flood-control reservoirs that lie in the Southwest and other parts of the country.

The writer believes that the snow-survey data, thus collected, will induce its extension until all the major streams, at least in the West, have sufficient courses established and under observation to enable their performance for the following season to be known. The purpose is not in terms of a snow survey to determine merely how much snow lies on the ground, but wholly as a point on a definite curve from which one can forecast the probable run-off from that stream during the following year. A long-time accumulation of such points gives a curve of reasonable accuracy.

Howard T. Critchlow,[36] M. Am. Soc. C. E. (by letter).—It is scarcely necessary to emphasize the importance of the collection of fundamental data to which Mr. Wolman refers as the bookkeeping of the water-resources problem. There is an economic aspect to this problem, namely, that its solution requires money and that such money must be obtained, in most cases, from Government agencies. The writer has had a little experience with trying to get money from State legislatures for this purpose in order that the State may co-operate with the Federal Government in the collection of this necessary information. Engineers who appreciate the importance of these fundamental data, should make that fact known to the people who have control of the "purse strings" in the Federal Government and in the State Government. It does not require large sums, but it does require sufficient money to increase the facilities for collecting this information. This subject is discussed at some length,[37] in a report of the National Resources Committee on "Deficiencies in Hydrologic Data."

[35] Senior Irrig. Engr., U. S. Dept. of Agriculture, Berkeley, Calif.

[36] Engr. in Chg., State Water Policy Comm., Trenton, N. J.

T. T. KNAPPEN,[38] M. AM. SOC. C. E. (by letter).—One gains the impression from reading the interesting group of papers in this Symposium that flood-control engineering is as yet a poorly developed branch of the profession. The economic aspect of the problem seems to be the least developed in the opinion of most of the authors, although the engineering side provokes a rather varied discussion. There is manifested a feeling that the problem must be dealt with on broader lines than in the past, that technically it must be considered as a major problem in stream planning and development, and that, economically, new values must be reflected in the determination of justification if the popular demand for adequate protection is to be met.

These demands point the need for a critical overhauling of the methods of handling these problems in the past and, to-day, there is every evidence of this development in that section of the profession connected with flood control. Essentially, the problem may be divided between: (1) Hydrological studies, concerned with snowfall, rainfall, run-off, and flood characteristics; (2) planning, which includes the investigation and design of flood-control structures, such as reservoirs, walls, dikes, floodways, and channel improvements; (3) flood routing, which is used to determine the effect of such works on flood stages; and (4) economic studies, which determine the justification for the construction of flood-protection works and relative merits of the various plans considered.

Hydrological Studies.—The recent experience with disastrous floods on many of the important rivers of the United States has modified the American engineer's ideas as to the probabilities of their occurrences. Many engineers now are dubious of the value of frequency studies developed on the short recorded experience available, particularly in view of the constantly changing condition of water-shed development. A natural development is an investigation in the meteorological field that will indicate the possibilities of maximum precipitation conditions and a possible upward revision of intense rainfall frequencies. Another major consideration is the change in water-shed development that has been occurring over many years, the determination of its effect on run-off, and a consideration of curative or alleviating measures. The necessity for more basic data along these lines is apparent to every engineer dealing with these problems, and it is to be hoped that the curtailments that have resulted in the partial cessation of these activities in many parts of the country will come to an early end.

Planning.—Rarely to-day does one hear of proponents of levees, reservoirs, or channel improvements declaring that their method is the only one to use. On the other hand most engineers realize that any major plan may combine all of these, as well as other methods, such as floodways, outlets, and water-shed control. Furthermore, it is becoming more apparent, as emphasized by several of the authors, that flood control cannot be separated from other developments in water conservation and must be considered in civic planning and regional development plans.

---

[37] Rept. of the Special Advisory Committee on Standards and Specifications for Hydraulic Data; Submitted by the Water Resources Committee on April 18, 1936, to the National Resources Committee.

[38] Associate, Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

Mr. Uhl has indicated that, in the New England States, flood control can be secured as an incident to power development with a reasonable degree of safety. Others may question the dependability of such control, but regardless of individual opinion, at least in many instances economic planning requires that the two be considered together. Another important factor is the need for increased stream flow for sanitary reasons which may justify a greater measure of conservation than power alone. The reasonable combination of these needs with those for flood control, together with a careful economic valuation of available storage and its most beneficial use, is an important regional problem. The solution of such problems has an important bearing on the planning of flood-control structures.

Flood Routing.—Only through accurate flood routing can the effect of flood-control works be determined and their economic justification established. Messrs. Morse and Thomas take a rather pessimistic view of the developments along this line and suggest that model studies under way at the Carnegie Institute of Technology, in Pittsburgh, Pa., offer the best solution to this problem. They seem quite hopeful that these models will give accurate results in the determination of the effectiveness of proposed works. Although the writer feels that the use of these models is unquestionably a wise move and that they will give valuable results, he is also of the opinion that recent developments in the analytical handling of these problems have eliminated their objections partly and that excellent results are now being obtained with the methods developed on the Muskingum flood-control project, in Ohio.

It should be emphasized that the analytical flood-routing methods can be checked by applying them to known past floods. When properly made, these checks have resulted in accurate reconstruction of past floods. This procedure seems parallel to that used in the model studies, in which the model is adjusted for known past floods.

The analytical method is based upon the principle that constant ratio exists for any reach of the river, between the valley storage in the reach and a weighted flow determined from inflow and outflow. The equation may be written,

$$K = \frac{t\,[0.5\,(i_2 + i_1) - 0.5\,(o_2 + o_1)]}{X\,(i_2 - i_1) + (1.0 - X)\,(o_2 - o_1)} \quad \ldots\ldots\ldots\ldots (3)$$

in which K = ratio of storage increment in the reach, in day-second-feet, to corresponding weighted flow increment, in cubic feet per second; t = time unit of computation, in days, or in fractions of a day; X = fraction of weighted flow increment that is derived from the inflow increment; i_1, i_2, etc. = total instantaneous inflow, in cubic feet per second, to a reach at the beginning of successive time units (t); and, o_1, o_2, etc. = corresponding instantaneous outflow to a reach at the beginning of successive time units. The numerator in Equation (3) is the storage increment, in day-second-feet, and the denominator is the corresponding weighted flow increment, in cubic feet per second. If the denominator is rewritten in the form: $(o_2 - o_1) + X\,[(i_2 - i_1) - (o_2 - o_1)]$, it is apparent that the first term represents the "prismatic" storage below the normal surface slope, and the second term represents the "wedge" storage increment. It will be noted that this eliminates at least part of the objection expressed by the authors to the analytical method. This method was brought to its present development by Thomas S. Burns, M. Am. Soc. C. E., and Frank B. Harkness and G. T. McCarthy, Assoc. Members, Am. Soc. C. E., in the flood-routing studies on the Muskingum project.

The analytical flood-routing method as now applied is believed to give fair results on the main stems of important rivers but in most cases its application is not practicable on the tributaries particularly where many streams of about the same relative importance are coming together. For such cases, some method of developing modified hydrographs for reservoir systems is needed, which will account for the location and the collection characteristics of the controlled areas as well as their extent. Possibly, the technique of model analyses can be developed for the accurate solution of such cases. At the same time there is a need for an analytical method that can be used at least for preliminary studies.

Economic Studies.—Mr. Jacobs states that: "The construction of flood-protection projects on a monetary economic basis alone is a thing of the past. Where the lives of human beings are endangered and where great suffering may occur as the result of floods, protective works should be constructed." This statement is qualified later in the paper by the following: "It is also essential that those who must pay for the protective system have full knowledge of the cost, of what burden they must bear, and of what security the final developed plan provides."

On the other hand Mr. Uhl states,

> "Attempts have been made to rationalize the second problem, namely, that of flood prevention or reduction, on a purely economic basis. If definite information were available, the solution would be relatively simple; the maximum expenditure economically justified to prevent recurrence of certain flood damages would be the capitalized present worth of the damages over the period of flood frequency causing them."

Somewhere between these points of view the answer to the problem must lie. Taking the case of an individual community planning to protect itself, it can determine its policy knowing the costs and the degree of protection. The people of that community may see more to the problem than the capitalized value of average annual damages. They may do as the people of Dayton did, after the 1913 flood—envision a blighting of their community, an almost complete abandonment of the flooded areas, with the loss in private investments therein far in excess of the capitalized annual direct and indirect flood losses based on frequency calculations.

Cities such as Pittsburgh, Pa., Hartford, Conn., Binghamton, N. Y., Springfield, Mass., Wheeling, W. Va., Cincinnati, Ohio, Louisville, Ky., and Paducah, Ky., can take little satisfaction from statistical computations that show the average annual losses to be small based upon frequency studies. They are faced with the plain facts of tremendous property depreciation and restricted development, creating a situation in which the assurance of protection against future floods has a value in excess of the capitalized average annual value of flood losses.

The writer would like to suggest that the answer to the problem lies neither in the abandonment of all economic rules nor in the strict application of the criterion of capitalized value of average annual flood losses in the accepted sense, but rather that it may be found in the determination of benefits which may be concerned with the restoration or maintenance as well as the appreciation of property values depreciated by flooding, with an added evaluation of the benefits to Government property and of the benefits due to elimination of indirect damages outside the flooded areas. This attitude is based on the assumption that the intangible values not ordinarily evaluated, such as fear of loss of life, mental distress, tendency to abandon flooded areas, etc., as well as direct flood losses, are reflected in such depreciation.

The evaluation of these benefits although difficult, may be worked out and the need for flood protection established in such places as the Ohio River, Connecticut River, and Susquehanna River Valleys where recent disastrous floods have demonstrated the vulnerability of the valley towns. On the other hand, may there not be many other places as vulnerable that have not felt the disaster of a major flood to "drive home" the necessity for, and value of, flood protection? Despite the previous floods, the citizens of Pittsburgh were not sufficiently flood-minded before 1936, to demand protection and to be willing to pay at least part of the costs. Prior to the 1937 flood, it would have been most difficult to convince the people of Louisville or Paducah that their cities were in danger of serious flooding. Certainly, there is a necessity for the development of sound engineering and economic methods for determining need for protection, not only for places which floods have attacked, but also for those places which, although equally vulnerable, have not felt the scourge of a major flood in recent times.

Assuming that the need for flood protection can be evaluated on a broad enough basis to justify protection for the more populated sections, it should be possible to apply the developed data to the internal economics of various projects. There are many problems to be solved therein, such as the relative balance between reservoirs, channel work, and levees, the economic size for any reservoir, the height to which levees should be built, etc. The solution of these problems requires the careful development of the basic data by zones and elevations as well as extensive flood-routing studies to assign values to the units under consideration. Furthermore, frequency studies are necessary as a basis for the determination of average annual values.

The economic problem is not a simple one in any case and on large river systems becomes highly involved; but only by the application of thorough field investigations and office studies can adequate and sound economic, as well as engineering, studies be developed.

M. C. TYLER,[39] M. AM. SOC. C. E. (by letter).—An excellent account of the situation with respect to flood-control work by the Federal Government has been given by Colonel Covell. He has traced the legal and legislative procedure through which the United States has passed to reach the stage at which the Congress has authorized many worthy and beneficial projects for the protection of lives and property from the ever-recurring ravages of excessive flood flows caused by periodic extraordinary precipitation.

It was inevitable that, sooner or later, the people would demand that the National Government assume some obligation for the protection of citizens from the injuries and devastations caused by floods which frequently arouse so much human interest, first in one section of the country and then in another. Flood-control works, of necessity, affect the navigation of rivers in some manner, and it is logical that the Federal Government should accept its proper function with respect to flood control.

The Constitution of the United States confers upon Congress the power "to regulate commerce with foreign nations, and among the several States, and with the Indian tribes," and by this provision there was transferred from the States to the Federal Government the control of all the navigable waters of the country for the purpose of navigation. At first, it was seriously doubted whether the power to regulate, comprehended the right to improve; that is, whether the improvement of rivers and harbors was a subject of national concern and of constitutional appropriation. In May, 1824, Congress passed the first Act to improve navigation entitled, "An Act to Improve the Navigation of the Ohio and Mississippi Rivers." About that time the luminous decision of Chief Justice Marshall, in the case of Gibbons *vs.* Ogden, established clearly and indubitably the power of Congress with respect to the waterways of the country which could carry interstate commerce, and removed completely the doubts of earlier years. That decision of the Supreme Court of the United States marked the birth of a permanent Federal policy of river and harbor improvement—a policy which has grown from year to year with the increase of population and needs of commercial transportation. Now, flood control also has been made a national activity by Federal law.

The general flood-control bill approved June 22, 1936, and the Overton Flood Control bill approved June 15, 1936, were studied for a period of almost two years by committees of Congress. They were based on the reports of the Chief of Engineers containing the results of studies extending over a long period of years. The Mississippi River Commission is continuously engaged in studying the flood-control problem on the lower river, and advance planning for additional works necessary to provide full protection has continued with the prosecution of the works authorized for construction by Congress. The voluminous and comprehensive data presented in the reports of the Army Engineers[40] provide the principal basis for national planning with respect to the development of water resources. They permit the preparation of a program for such development on a scale limited only by advisable expenditures. This program may go hand in hand with the development of land resources, reforestation, and measures for the prevention of erosion and retardation of run-off. It is very seldom that major flood-control structures conflict or interfere with other water uses.

---

[39] Brig.-Gen., Corps of Engrs., U. S. Army; Asst. to Chf. of Engrs., War Dept., Washington, D. C.

The Flood-Control Act of June 22, 1936, embarked the Federal Government on a flood-control program which is destined to develop in an economic and orderly manner so as to afford great and lasting improvements throughout the land for the preservation of lives and property and the betterment of living conditions generally.

Since the enactment of the general Flood Control Act, the Army Engineer organization has been working vigorously in making detailed plans for beginning construction by contract of the flood-control works authorized. The War Department will be ready, when funds for actual construction are appropriated, to begin work without delay. In the design of dams and appurtenant works, the Chief of Engineers is fortunate in having the assistance of many of the ablest and most experienced consulting engineers in the United States, and hopes to secure the services of others as the need develops. Much help is also being afforded through co-operative arrangements with other Departments and with the hydraulic laboratories of universities.

Although the planning of flood-control works by the Federal Government is in a most favorable and constructive situation, this does not mean that everything desired is already accomplished. There is much hard work to be done, and innumerable difficult problems to be solved. However, the ground-work has been well laid. Questions of local co-operation as to financing appear difficult, but they can be solved with patience, judgment, and co-operative thinking.

Gordon R. Williams,[41] Assoc. M. Am. Soc. C. E. (by letter).—In discussing the economics of flood control, Mr. Uhl states that, on a purely economic basis, the justified expenditure for the prevention of flood damage caused by a flood of a certain magnitude and frequency "would be the capitalized present worth of the damages over the period of flood frequency causing them." It seems desirable to clarify the procedure implied for the determination of future damages for which the present worth is to be obtained. There may be situations in which too much reliance on the figure for past damages would erroneously justify too large an expenditure for flood protection and then, again, it might lead to an entirely inadequate expenditure. As an example of the former situation consider the Winooski River Valley which is mentioned by Mr. Uhl.

---

[40] House Doc. No. 308, 69th Cong., 1st Session.

[41] Associate Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C. Submitted with the approval of the Director, U. S. Geological Survey.

The reconstruction that occurred in the Winooski River Valley after the flood of 1927 was undertaken with the intent of avoiding, as far as possible, a repetition of former damages. Consequently, highways were relocated on higher ground, concrete and steel truss bridges with large openings replaced light bridges with inadequate openings, spillways of dams were enlarged, and many people rebuilt their homes on higher ground. The result is that if the flows of 1927 occur again, the damage in the Winooski River Valley will not be as great as it was in 1927. In other words, some of the justified expenditure for the control of flood waters was spent at the time of reconstruction. Of course, if flood-control measures are adopted immediately after a flood there may be a different policy in regard to expenditures for reconstruction, but if reconstruction has already taken place weight should be given to the situation just considered. A similar situation may exist in other communities where there has been a permanent decrease in the value of property which lies in the path of flood waters.

In contrast to the foregoing example are the more numerous arguments for using, as a basis for computing justified expenditures, a value that exceeds past damages from the greatest flood. Again, taking the Winooski River as an example, one finds, that the U. S. Army Engineers computed that an expenditure of $433 000 was justified for protection against the 100-yr flood. However, this sum should be increased because a structure which protects against the 100-yr flood also protects against damage caused by the smaller but more frequent floods. Actually this was done and the justified expenditure was increased to $1 055 000.

The problem of increasing the justified expenditure because of a possible increase in the value of property which will be benefited by flood control is analogous to the one of determining, theoretically, the justified expenditure for a trunk-line highway. Roughly, the procedure is to take a traffic count of vehicles that use existing facilities, and then compute the resulting revenue in taxes that will come from the sale of gasoline used by the vehicles. Obviously, this does not give a true picture of the situation which will result from the construction of the road because there is little doubt that the volume of traffic will exceed the original traffic count and, in addition, there will be an almost indeterminate saving to private individuals and to industries that benefit by the construction of the road. The original estimate of justified expenditure must be increased, but how much?

A comparable situation exists in flood-control planning. If reasonable protection is given to river valleys, the cities and towns affected may grow, industries may be attracted, property values will doubtless increase, and the wealth of the individual citizens will be augmented. In such cases the figure for the past flood damages becomes entirely inadequate as a basis for determining the price to pay for future protection.

This discussion has considered the purely economic justification without any allowance for the humanitarian aspect stressed by Mr. Jacobs. There is no question but that this consideration should be stressed, but not to the point where a community assumes a burden which may even threaten its financial ability and thereby interfere with the fulfillment of its normal commitments. Experience may prove that in some cases the soundest method to pay for future damages will be to establish an insurance fund maintained at least in part by small premiums paid by those who cannot, or will not, move out of danger.

ARTHUR T. SAFFORD,[42] M. AM. SOC. C. E. (by letter).—Engineers working on designs of river structures, officials and operating men in hydro-electric power stations, and owners and managers of industrial plants located on New England rivers will find the paper by Mr. Uhl extremely valuable, not only because of the important data, but because of its arrangement and the accurate conclusions contained therein. One must have had the experience of living and designing structures in and on New England rivers to interpret properly flood records. One needs only to read over the newspaper accounts and early reports of the 1927 and 1936 floods, to realize how little was known at the time about their causes, and the lessons to be drawn from them. Unless records of river heights and conditions given out during a great flood are correctly reported by newspapers, or correctly broadcast, the result is to confuse and make it more difficult for the authorities to know when and how to act in protecting the public.

This is one of the many papers contributed by engineers far enough removed from the hysteria produced by the floods, to make them valuable as a permanent record. Even a year after the Great Flood (which name, for many years, will be given to that of March 20, 1936), opinions are expressed and plans made for eliminating future floods, which in many cases have no more basis than the hope that such a result is possible.

The writer's official responsibilities during the 1927 and 1936 floods were confined to the Merrimac River, at Lowell, Mass.; but he was in the employ of the Water Power Company there, during the floods of 1895 and 1896 mentioned by Mr. Uhl; and was familiar with the flood marks of 1785 and 1852. At Lowell, there are on record six or more floods during 150 yr which registered 10 to 13.5 ft on the Pawtucket Dam, and about 15 ft of back-water, but which did little damage beyond the quiet flooding of streets, cellars, and mill basements. Machinery and household goods, and goods in process left on the machines were inevitably wet; but the protective margin of a few feet above the peak of these floods was sufficient to leave intact all hydraulic structures of the Company, due to the foresight of Mr. Francis, by installing the Francis gate,[43] before the famous 1852 flood, as a result of his careful studies of former floods.

---

[42] Engr., Proprietors of Locks and Canals on Merrimack River; Cons. Hydr. Engr., Lowell, Mass.

[43] *Civil Engineering*, February, 1937, p. 143.

The flood of March 20, 1936, on the contrary, which registered a final height of 102.02 ft, or 20.02 ft above the crest of the Pawtucket Dam, and 6.5 ft above any previous peak, produced an additional 8 ft of backwater. For the first time the Merrimac River was not held within its ordinary flood channel, but broke through at several points, went entirely out of bounds, and isolated large sections of the city. It was only prevented from wrecking parts of the business center of the city, by a skeleton dam, 3.5 ft above the Francis gate, and a timber and sand-bag dam across the railroad right of way into the city from the north (see Fig. 18).

After the water subsided, it was found that the city had had a very narrow escape from lasting injury. The great mass of fill accumulated over a period of 100 yr and more over low areas on the banks of the river or dumps was gone; many neighboring buildings were wrecked; certain streets in the path of the flood were left with half the buildings either moved or wrecked; the great Northern Canal wall of the Proprietors of Locks and Canals (which had been overtopped for the first time in its history) suffered serious injury in several places; and most of the conduits carrying electric power to the river mills were so thoroughly wet that for nearly a year thereafter, weak places kept appearing and had to be replaced.

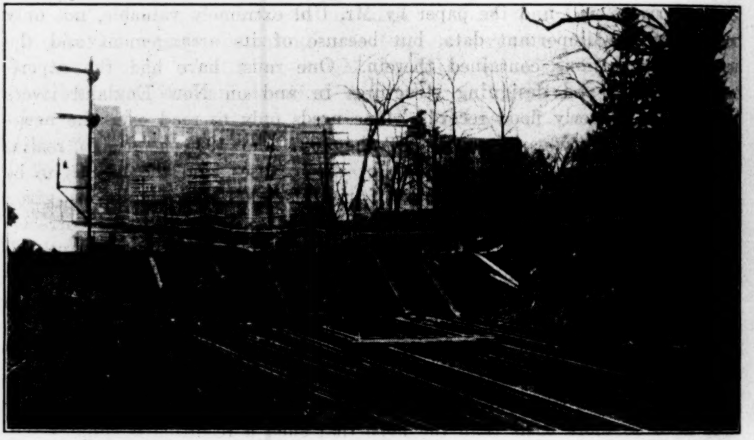

FIG. 18.—SAND BAG AND TIMBER DAM ACROSS THE BOSTON AND MAINE RAILROAD WEST OF LOWELL RAILROAD STATION.

All these structures belonging to the Water Power Company and the industrial plants on the river, were repaired before the end of the year, although much of it had to be done by continuous week-end operations. Fig. 19 shows the repair work in progress, the unfinished part indicating the nature of the break.

From personal examination and published reports by utilities, insurance authorities, and others, apparently these same conditions, both during and after the Great Flood, obtained at Concord and Manchester, N. H., and at Lawrence and Haverhill, Mass.

The fact that, in the 1936 flood, the stage was 6.5 ft higher, and the quantity of water 65% greater than any previous flood, with existing margins of safety wiped out, would appear to make some improvement necessary if these communities are to survive without the anxiety of a repetition of this situation.

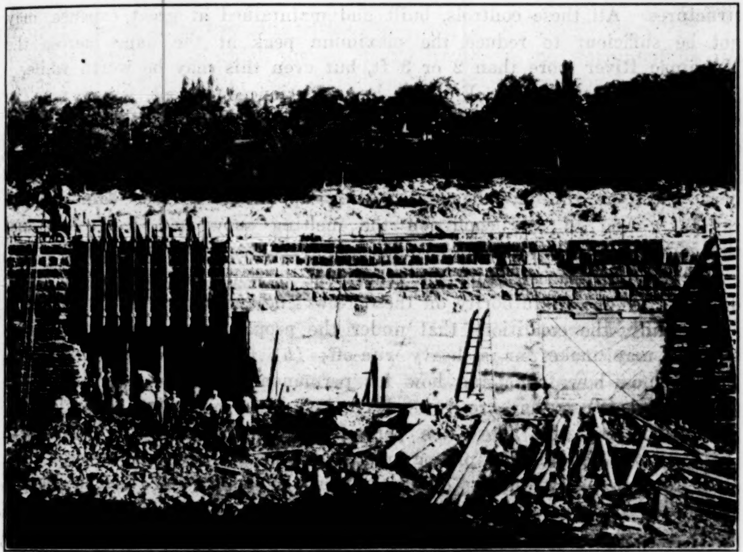

FIG. 19.—ABOUT THREE-QUARTERS OF CANAL LINING REPLACED; REMAINING QUARTER OPEN SHOWING CHARACTER OF BREAK.

Any study of flood control for New England rivers would seem to require a knowledge of what quantity and height of water had occurred prior to this 1936 flood; what additional burdens this flood had placed on the industrial cities; and what reasonable improvements could be made in the nature of reservoirs, channel improvements, and dikes, to bring the local control down to the situation as it prevailed during 150 yr or so prior to 1936. For Lowell and the Merrimac River, this means a peak run-off of not more than 100 000 cu ft per sec instead of 173 000 cu ft per sec; a depth on the Pawtucket Dam of not more than 13.5 ft instead of 20 ft; and a corresponding reduction of 8 ft in the height of the backwater below the city.

Assuming flood reservoirs to be actually empty and 100 000 cu ft per sec to be the maximum at Lowell, and the 17 500 000 000 cu ft of natural flood pondage above Lowell, Manchester, Concord, and Bristol, N. H., to be not reduced, the equivalent of two additional Lake Winnepesaukees would be required.

Mr. Uhl wisely refers to several "partial" solutions, and they should be more generally considered as such. The promise of more than this simply deceives the public who must pay the bill, either by assessment or taxation. These structures may be storage reservoirs, improved channels and dikes, and free channel bridges instead of reinforced concrete arched structures. All these controls, built and maintained at great expense, may not be sufficient to reduce the maximum peak at the dams across the Merrimac River more than 2 or 3 ft, but even this may be worth while.

In recent years, New England has experienced storms which may be called torrential, and such storms appear to be inevitable both locally and over areas of several thousand square miles. They make the White Mountains and the Green Mountains look more and more like the roof of a barn with the run-off, ultimately, being approximately the same as the rainfall. Add to this condition the melting snow and ice cover, and the conditions existing prior to March 20, 1936, are re-created.

As a lesson learned from the 1936 flood, it would appear that it is the duty of any one in authority on these New England rivers: (*a*) To understand, fully, the conditions that under the proper combination of circumstances, may make for a heavy run-off; (*b*) to have complete records; (*c*) to know how much and how far permanent structures will stand the strain; and (*d*) to have ready at least a skeleton on which to build temporary barriers well above the permanent structures. Office records in the form of diagrams and photographs should be available and studied from time to time, as freshets (even mild ones), occur; and lessons learned from each freshet should have their place in the records.

In addition, an important element in preparing for New England floods is time—time to transfer human beings, livestock, and necessary and valuable possessions to higher ground. In Vermont, in 1927, besides property damage approaching $40 000 000, there was a large loss of human life (87 were drowned, 55 in the Winooski River Valley), for the most part due to the suddenness of the rise of the water and the difficulty in maintaining communications.

Very few lives have been lost in floods of the Merrimac River although the time of rescue often has been short. The peak of the 1936 flood at Plymouth, N. H., was on March 19, from 8:00 A.M. until noon, and at Lowell on March 20, from 5:00 P.M. to 11:00 P.M.; but the Lowell peak had been forecast early on the morning of March 19, the Francis gate had been dropped, and work had begun on the protective dams above that point by 7:00 A.M.

The reports and predictions of flood heights from the up-stream stations, maintained by the public service companies and other authorities, were so frequent and reliable that not only could the highest points to be reached be estimated, but the length of the peak. There was ample time to warn officials of the city, the U. S. Works Progress Administration, Red Cross, State Police, and the National Guard; and as a result of the splendid co-operation which American people always have given when they know what and when there is an emergency, the City of Lowell did not have an appalling loss of life. It speaks for the value of the operating forces of the public utilities, beyond that of temporary activities. Most of the information broadcast by radio, in so far as it was insufficient or mistaken, probably increased the anxiety and may have done more harm than good. The radio can be made a splendid addition to the telephone and telegraph, if in the hands of proper authorities.

Some conclusions, which appear to the writer to be warranted by the experiences of the March, 1936, flood, and its record-breaking heights, flow, and currents, are:

(1) Engineers and others, concerned with flood work, should think in terms of maximum run-off, possible from heavy rains, warm weather, and melting snow, and not of what heights had been reached through a limited period of years. They should be "conditioned" to the idea of the 100-yr flood. The precipitation and water equivalent of the Pinkham Notch record for March, 1936 (29 in.) may occur the next time in almost any of the mountain valleys of New England.

(2) More records should be taken every half hour, or so, for the upper rivers and principal tributaries, as well as the main river stations, in order to be able to predict whether peaks will be distributed or be concentrated.

(3) Abutments should be higher; if the last few feet interfere with approaches to power or gate-houses, or if there are railroad cuts, such as those at Lowell, Mass., and Manchester, N. H., concrete ribs, with holes drilled for plank flash-boards, may be substituted. At the Old Guard Locks, at Lowell, an additional 3.5 ft above the Francis gate was taken care of without excitement by that form of construction, built after a study of the 1927 flood appeared to warrant it.

(4) Every growing industrial city or town, situated on a New England river, should have a map showing flooded areas for the maximum flood. This should be used as a picture in the acceptance of streets, in building bridges, in laying out sewers and in granting building permits. The occurrence of ice jams, accumulating pressure, and wrecking bridges and other structures, is always a possibility before the winter is over. No structures should be built which will add to the flood menace of any district.

(5) The valley storage which obtained during the 1936 flood from Lawrence, Mass., to Franklin, N. H. (estimated at 17 500 000 000 cu ft) was about 50% greater than the combined storage in Lake Winnepesaukee and other reservoirs that were already full and discharging before the danger of a higher peak was over. There is no advantage in depending upon flood reservoirs unless they are nearly empty before the extreme test which they are expected to meet.

(6) The duty of setting permanent markers on New England rivers for the 1927 and 1936 floods, should not be allowed to be forgotten. The fact

that the 1936 flood carried 65% more water than ever before, may make these records good for a century or more.

(7) Federal and State operating activities (such as the Weather Bureau, Geological Survey, U. S. Engineer Corps, State police, etc.) should have on file the records of the 1936 flood; and, at times of future floods, they should refer to the unusually good records of the utilities operating hydro-electric power stations as well as to their own. Snow records should be much increased in number.

This discussion does not do justice to Mr. Uhl's paper and is too personal. Having lived through the strain of the week and more of the floods that occurred from March 13 to 20; and afterward waiting for the full extent of the damage to be known and another two months before repair work could be begun, it is not easy to study any problem of flood control for the Merrimac River impersonally; but it leaves one with a profound respect for the forces of Nature, and the difficulty of competing safely with them.

The declivity of New England streams is in their favor. The Pemigewasset River, at Plymouth, could not have passed 65 000 cu ft per sec on March 19, 1936, or the Merrimac River, at Lowell, 173 000 cu ft per sec the next day, except for the slope maintained to produce the high velocities. Velocities as great as 20 ft per sec were not uncommon.

Local flood control by dikes, and river channel improvements on limited areas, should include the sewerage problem, because of many individual outlets into the river. When such outlets "back up" they can be even more dangerous to the public than quick flooding by clean water.

From the insurance standpoint: If the damage to the Merrimac Valley from the 1936 flood was roughly $20 000 000, and a flood of such intensity occurred only once in 100 yr, the sum of $400 000 at 4% compound interest would pay the equivalent at the end of 100 yr; if once in 200 yr, the sum of $8 000. There would appear to be a field for flood damage insurance, as it might be written by companies operating on a national scale, to protect at least a part of the investment in industrial plants, stores, warehouses, and their contents against loss.

W. G. HOYT,[44] M. AM. SOC. C. E. (by letter).—No city of the United States of equal size is situated so unfortunately with reference to rapid concentration of flood waters as is Pittsburgh, Pa.; yet, with respect to flood damage, Messrs. Morse and Thomas describe Pittsburgh as a "lucky city," a description that will be concurred in by all engineers who have studied cause and effect of major floods in the basins of the Allegheny and Monongahela Rivers However, there seems to be no valid reason why Pittsburgh's luck will always hold. Eventually, Nature's roulette wheel will record a double zero. When that occurs it is sincerely to be hoped that a catastrophe will be averted by means of a "superior type" of reservoir control combined with an efficient system of flood-forecasting.

---

[44] Hydr. Engr. (Prin.), Conservation Branch, U. S. Geological Survey, Washington, D. C.

Whether or not a super-storm can occur in the Monongahela and Allegheny River Basins simultaneously is a question which, perhaps, meteorologists will some day be able to answer. It is true that no such outstanding storm has thus far been recorded—the Miami (Ohio) storm of March 24 and 25, 1913, and the storm of January, 1937, having had their centers to the west, and the storm of March 17 and 18, 1936, to the southeast.

If any of these storms had been centered over the Upper Ohio River Basin greater floods would have resulted than the record-breaking flood of March, 1936. However, even if it is assumed that precipitation over the basin which has been recorded in the past is an index of future possibilities, Pittsburgh has thus far apparently been fortunate, and especially so in March, 1936. During February, 1936, there were three thaws in the Monongahela River Basin and one in the Allegheny River Basin which materially reduced the water content of the snow then on the ground. Conservative estimates indicate that the reduction in water content may have amounted to between 1 in. and 2 in. in depth over the Allegheny River Basin and to between 2 in. and 3 in. over the Monongahela River Basin. The minor flood peaks resulting from these thaws broke up and removed the unusually thick channel ice. To some extent at least flood run-off must have been reduced by increased infiltration as a result of the reduction of frost in the ground. All these conditions were favorable to Pittsburgh.

Messrs. Morse and Thomas refer to the turning of rain to snow above Oil City, Pa., during the storm of March 17 and 18, 1936. An analysis of the snowfall, rainfall, and run-off during the flood period discloses how important this freak of temperature was in lowering the flood crest. Apparently, much of the rain turned to snow not only in the Allegheny River Basin above Oil City, but also in the Monongahela River Basin above Morgantown, W. Va. The effect of this occurrence was materially to reduce the resultant run-off from that storm. That this condition existed is evidenced by the fact that in the upper basins of both the Monongahela and Allegheny Rivers the run-off during the period, March 20 to 31, after the flood crest had passed Pittsburgh, was in excess of the precipitation, indicating a postponement of run-off because of the snow of March 17 and 18, equivalent to possibly 2 in. in depth of water over the basins. The peak run-off during the period, March 20 to 31, in these areas, was greater than the peak run-off during March 17 and 18, when Pittsburgh was experiencing its maximum stage—a stage very considerably lower than that which would have occurred if the rain had not turned to snow over nearly half the drainage basins.

Messrs. Morse and Thomas seem to have departed from an excellent presentation of facts into the realm of conjecture when they referred to "the man-made floods." It is true, that at Pittsburgh, Man is occupying the valley and encroaching on the channel that Nature has designed to carry the floods and, to this extent, the flood damage is man-made. Getting into the way of a flood and being damaged by it however, are far different from making a flood. No evidence is presented to indicate that the flood of March, 1936, was increased as a result of changes made in forests or other vegetative cover of the basin, or as a result of any of Man's activities.

Do engineers play fair with the public who look to them for facts and advice if they lead the public to believe that Man is accountable for the excessive run-off of a major flood, such as that of March, 1936, in the Upper Ohio River or that the run-off following major storms, involving the unusual timing of the meteorologic events which create floods, can be controlled materially, except by engineering structures?

LT. COL. J. D. ARTHUR, JR.,[45] CORPS OF ENGINEERS, U. S. ARMY (by letter).—The present status of Federal flood-control projects has been fully outlined by Colonel Covell. It is to be noted that the system of reservoirs for flood control on the Ohio River, either authorized or under construction, is distributed over a wide area, on many tributaries. Little has been published as to the methods of operating this system to provide the maximum benefits.

The operation of the fourteen reservoirs now (1937) under construction in the Muskingum Valley will be placed in the hands of the Muskingum Watershed Conservancy District, a political sub-division of the State of Ohio. It is only human to assume that it will be operated to provide the maximum protection to the residents of the Muskingum Valley. However, will such operation provide the maximum protection to the residents along the Ohio River below Marietta? Engineers know that the Miami Conservancy District System provides full protection to the residents of that Valley, but they likewise know that, with its uncontrolled outlets, benefits to localities along the Ohio River will not necessarily accrue. In fact, it is easy to imagine conditions under which it might prove to be decidedly harmful.

When the system is extended to other tributaries, each with a local flood problem in its valley, does it not follow that, unless there is a single office with full authority to control operations on all tributaries, the system will not be operated for the greatest good of the greatest number? The construction of the system must be the primary objective, but studies should be initiated at once of the best methods of operation.

The problem is a difficult one, and it is not simplified by the requirements of local participation in costs. If the residents of the Muskingum Valley, or of Pittsburgh, for example, are taxed for a portion of the costs, might they not well ask why they should be interested in what happens at Cincinnati? Perhaps this phase of the subject did not receive proper attention when the policies enunciated in the Flood Control Act of 1936 were adopted.

JOHN H. MEURSINGE,[46] ASSOC. M. AM. SOC. C. E. (by letter).—Except China, there is probably no country in the world which has suffered so much from floods as the low lands along the North Sea, which are better known as Holland, or The Netherlands.

---

[45] Dist. Engr., U. S. Engr. Office, Zanesville, Ohio.

[46] Structural Designer, General Petroleum Co., Los Angeles, Calif.

The first levees in Holland were built by the Romans to protect their military highways. As the construction of levees has been continued ever since, a protective system has been developed, which probably has no equal in the world. It is small wonder that some Dutch engineers do not consider the levee system of the Mississippi as very effective; but in an interesting comparison between flood problems in Holland and in the United States,[47] C. E. W. van Panhuys, District Engineer for the Netherlands Government, states that engineers in the United States have done everything technically and financially possible for such a young country.

In connection with this Symposium, the question may be raised as to whether American engineers could benefit by Holland's long experience with floods. The answer is "yes," always bearing in mind the fact that the Dutch engineers are mainly concerned with delta problems, so that dams and reservoirs are of minor importance to them. The purpose of the collapsible dams constructed on the Meuse River about 1917, was to improve navigation in summer. They are made to disappear during the flood season.

Furthermore, the area considered is rather small—about one-five-hundredths of the Mississippi River water-shed. However, it is not the size that counts, but the effectiveness of the protection system. Since about 1880 human lives have scarcely ever been lost in Holland on account of floods.

For each river, the Dutch engineer defines two channel sections: The so-called winter section and the summer section. Both are protected by levees. The small dikes along the summer section simply protect the valuable grazing grounds in the winter section against the summer flash floods. The winter section is from 1 500 to 3 000 ft wide, and the summer section from 450 to 675 ft wide. Within these sections no encroachments are allowed except brick kilns, which may excavate enough clay to equal the volume of the buildings they occupy.

Occasionally, a severe flood will overtax the winter section and spillways are provided to meet this emergency. To understand the function of these spillways the geography of the Meuse-Rhine delta must be considered. Most of the lands have elevations which vary between the low-water and high-water stages of the rivers. If a dike collapses much land would be threatened with submersion except for the fact that it has been divided into many different diking districts or "polders," each of which are protected by minor levees. Such a "polder" is an administrative unit, administered by the property owners themselves. They are under the supervision of the provincial authorities, however, who create and consolidate the districts if desirable. The district maintains all its levees, makes minor repairs, and operates the pump-houses which take care of the drainage of the seepage water.

---

[47] "Overstroomingen langs Ohio en Mississippi", *Ingenieur,* Royal Inst. of Netherlands Engrs., March 5, 1937.

In case of a dangerous flood, each "polder" sends its guards to the dikes. Their services come under the control of the engineers of the Netherlands Government who take charge of the entire river as long as the emergency lasts. If a dike threatens to collapse, or actually breaks, the engineers have the same authority as is generally granted to military commanders in time of war.

The advantage of many diking districts is obvious. When a spillway discharges its water over the dike, it submerges one "polder" only. This district is occasionally sacrificed for the benefit of the others.

In spite of these spillways, breaches in dikes still occur. Hence, each district has been provided with a so-called "terp." This is nothing but a properly located levee, which is high and large enough to take care of the population and live stock of the "polder" in case the district happens to be flooded. Frequently, the church and some public buildings are located on the "terp"; and it hurts no one's feelings when the church is converted into a cow barn during times of emergency.

The methods of making emergency repairs have changed very little in the past hundred years. The first sign of danger is an increased seepage flow in the dike. This water is likely to wash away so much of the material that all the fingers of all the Dutch boys would be unable to stop it. Mats made of willow branches, staked down on the inside talus of the dike, are more effective. They keep the material in its proper place, at the same time allowing a free flow of seepage water. This method does not cause any increased water pressures inside the dike, which might produce a breach.

Although breaches seldom can be stopped until the floods have passed, occasionally the "hay-wagon" may solve the problem. One or several wagons tightly packed with hay are dumped, wagon and all, in the breach. Whereas a more solid material would be swept away immediately by the in-rushing waters, the hay permits water to flow through, and the wagons may form a foundation on which sand bags can be piled for temporary repair.

Most of the breaches in Holland have occurred in the dikes along the Meuse, the most troublesome river in The Netherlands. In its low stage the run-off may be as low as 7 000 cu ft per sec, and in its flood stage as high as 100 000 cu ft per sec.

In 1923, the construction of a series of collapsible dams was begun to improve navigation conditions in summer. While this construction was at its peak a run-off occurred which was 15% greater than the previous recorded maximum. It flooded all the works and broke levees everywhere.

The cause of this unusual occurrence has been explained in a report by the late Dr. C. W. Lelij,[48] submitted when he was District Engineer for The Netherlands Government. Dr. Lelij's investigation showed that deforestation and newly cultivated lands had had no important influence on this run-off, because the average run-off of the floods had been decreasing in the previous fifty years.

---

[48] "Rapport betreffende de Verbetering van de Maas voor groote Afvoeren", door Dr. C. W. Lelij, Hoofd Ingenieur van den Rijkswaterstaat, s' Gravenhage, *Algemeene Landsdrukkerij*, 1926.

This remarkable flood was caused by the following conditions: From November 24 to December 20, 1925, much snow had fallen in the mountains of the Meuse water-shed. Immediately thereafter a heavy thaw had set in, and simultaneously a heavy rain soaked the entire shed. Remarkably enough, the peak of the storm moved with the peak of the flood from the south to the north.

In other words the determining factor in this flood was the weather; and as no one has yet learned how to control the weather, the Dutch engineers (who have accumulated an enormous mass of run-off data) are as much "in the dark" concerning the possible maximum run-off as their American colleagues. The authors of the Symposium suggest the gathering of more data, but the writer believes that the value of data should not be overemphasized, because some of the floods of the future may be much worse than data will ever reveal.

This is not the only important consideration stressed in Dr. Lelij's report. It calls attention to the fact that the bottom of the winter section of the Meuse River was rising at a rate of 2 mm (0.08 in.) per yr. In the past 750 yr, this bottom has risen 5 ft.

At some other places conditions were worse. At the end of the Nineteenth Century many railroad bridges had been built. To compensate for the piers the area of the winter section had been increased by excavating the channel. In 1926, when Dr. Lelij's report was published those places had been entirely filled in again. This condition, undoubtedly, had contributed its share to the higher floods.

American engineers probably never will know the possible maximum run-off of the Ohio or Mississippi Rivers. In the centuries to come the lands adjacent to the river, which are flooded regularly, will become higher also; and the floods, subsequently, will grow more severe. Undoubtedly, there will be flood disasters as long as people keep making homes along rivers. As a perfect protection system seems an impossibility, it may be advisable to consider first a more adequate protection of human lives. It may be worth while to spend some money in creating an efficient emergency organization that could be mobilized on short notice. Places of refuge, where the flood victims could find temporary shelter, may fit in to this plan, and although from a technical and economic standpoint the results may not seem great, the most important part of the job would have been done at a relatively small cost.

H. K. Barrows,[49] M. Am. Soc. C. E. (by letter).—A clear picture of flood conditions in New England, a very full discussion of the interesting features of the flood of March, 1936, and much information about earlier great floods are contained in the comprehensive and excellent paper by Mr. Uhl.

The flood of November, 1927, centering principally in Vermont, Northern New Hampshire, and Massachusetts, was due to excessive rainfall, reaching a maximum of probably 12 in. in the Green Mountains and resulting in especially high run-off from the smaller streams. Some noteworthy data are given in Table 10(a). The flood hydrograph[60] in these cases was approximately triangular in form, beginning at about 2% of the peak flow, rising uniformly to 100% at the twelfth hour, and then decreasing uniformly to 20% of the peak flow at the thirty-sixth hour. This would correspond to total flood run-offs, as shown in Column (4) Table 10(a), ranging from about 17 in. for the smaller drainage area to 6.5 in. for White River (695 sq. miles).

---

[49] Prof., Hydr. Eng., Mass. Inst. Tech.; and Cons. Engr., Boston, Mass.

TABLE 10.—NEW ENGLAND FLOOD DATA

Stream (1)	Drainage area, in square miles (2)	Maximum discharge, in cubic feet per square mile (3)	Approximate total flood discharge, in inches (4)
(a) FLOOD OF NOVEMBER, 1927			
Ellis River, near Jackson, N. H	28	528	17.0
Jail Branch, East Barre, Vt	38	303	9.7
Baker River, near Wentworth, N. H	52	288	9.2
White River, near West Hartford, Vt	695	202	6.5
Winooski River, near Essex Junction, Vt	1 000	111	3.6
(b) FLOOD OF MARCH, 1936			
North Branch of the Hoosac River, near North Adams, Mass	39	99	17.6
Middle Branch of the Westfield River, near Goss Heights	53	160	....
East Branch of the Pemigewasset River, near Lincoln, N. H	104	164	20.2
Deerfield River, near Charlemont, Mass	180*	180	....
Connecticut River, near Montague, Mass	7 840	28.9	8.8
Merrimac River, near Lowell, Mass	4 424	39.1	9.9

* Omitting the controlled area of 182 sq miles up stream from Harriman Reservoir.

As will be noted from Fig. 3, the unit flow of White River is materially in excess of the enveloping curve presented by Mr. Uhl, indicating the unusual magnitude of this peak flow for such an area. This is probably due, in part at least, to the shape of the drainage area of this stream, which has three approximately parallel tributaries tending to concentrate flood flows in the lower river.

The flood of March, 1936, was due in part to heavy precipitation and in part to melting snow, and it covered a much larger area than that of 1927, resulting in what may be called a "main river" flood of unusual magnitude, but with tributary streams at lesser peak flows than in 1927. Table 10(b) shows a few of the peak flows and total flood run-offs.

The Lower Connecticut River flows exceeded those of 1927 by about 33% at Montague City, Mass., and 42% at Thompsonville, Conn. On the Merrimac River, at Lowell, Mass., the peak flow of March, 1936, exceeded by 67% that of the previous highest (in April, 1852).

The writer has made a study of flood frequency on the Lower Connecticut River, a graph of which is shown in Fig. 20. Records of yearly flood flows are available for the period, 1880 to 1936, at three Massachusetts stations, Holyoke, Sunderland, or Montague City. A record of flood stages at Hartford, Conn., extends back to about 1801 and by a plot of flood flow, in cubic feet per second per square mile, at one of the foregoing three stations to flood stage at Hartford, it was possible to relate the latter to the flood flow at these stations (about 8 000 sq miles of drainage area).

---

[60] Rept. of the Cons. Engr. to the Advisory Committee of Engrs. on Flood Control, Vermont, 1928.

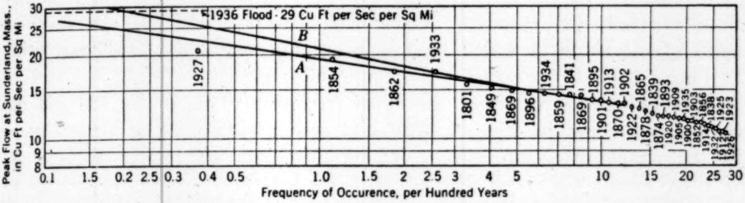

FIG. 20.—FLOOD FREQUENCY CURVE, CONNECTICUT RIVER, AT SUNDERLAND, MASS., 1801–1935.

In this manner all peak flood flows of importance were determined approximately for the period 1801-1936, or 136 yr, upon which the plot of Fig. 20 was based. Two interpretative extension curves are shown on Fig. 20. Curve *A* gives weight to the five or six upper points whereas Curve *B* is a more conservative interpretation, giving little weight to the 1927 point and to the other relatively high points.

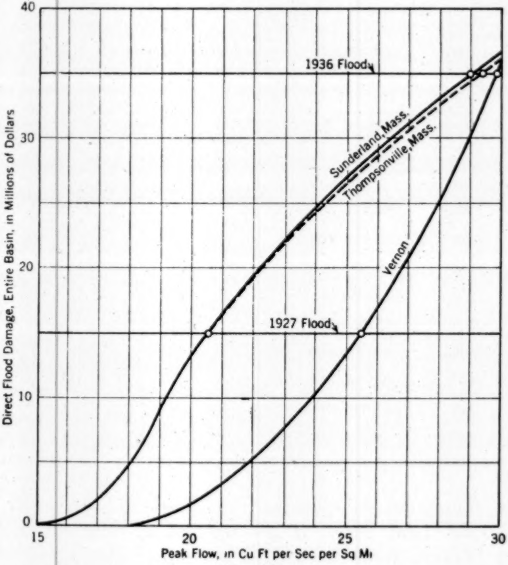

FIG. 21.

This shows the flood of 1936 (not plotted as a point) to have been the actual greatest based upon observations for about 150 yr of record, and by inference from the plot it would have a frequency of about once in 500 yr. The 1927 flood shows a frequency of about once in 90 yr.

On Fig. 21 are plotted peak flood flows in the Lower Connecticut River, at Sunderland and Thompsonville, against direct flood damages; a curve is also shown using Vernon, Conn., as an index station. In each case these curves have three points for their definition: (1) Damages in the flood of 1936; (2) damages in the flood of 1927; and (3) the stage or point of discharge at which flood damages are negligible. This last point has been fixed by personal experience and judgment.

Combining the results of the upper extension curve in Fig. 20 and the Sunderland curve in Fig. 21, Table 11 was prepared. The various steps in the computations are obvious and require no further explanation. As will be noted, the lesser half of the flood stages contributes mostly to the average yearly flood damages because, although flood damages are not relatively high, their greater frequency of occurrence effects a relatively larger yearly increment of damage. A flood of the order of that of March, 1936, with about 29 cu ft per sec per sq mile, has a high damage ($35 000 000), but its frequency is so rare that the yearly increment of damage from such a flood is relatively small.

TABLE 11.—DETERMINATION OF YEARLY DIRECT FLOOD DAMAGES, CONNECTICUT RIVER BASIN

Peak flood discharge, in cubic feet per second per square mile (8 000 sq. miles)	Flood frequency years, (from Fig. 20)	Direct damage, in dollars	Increment of damage, in dollars	Average frequency, in years	Yearly increment of damage, in dollars	Average yearly flood damage, in dollars
15	19	0				0
			700 000	23	30 000	
16	27	700 000				30 000
			1 500 000	31.5	48 000	
17	36	2 200 000				78 000
			2 500 000	41.5	60 000	
18	47	4 700 000				138 000
			4 300 000	55	78 000	
19	63	9 000 000				216 000
			4 000 000	72	56 000	
20	81	13 000 000				272 000
			6 600 000	105	63 000	
22	130	19 600 000				335 000
			5 400 000	165	33 000	
24	200	25 000 000				368 000
			4 200 000	250	17 000	
26	300	29 200 000				385 000
			3 800 000	365	10 000	
28	430	33 000 000				395 000
			4 000 000	510	8 000	
30	590	37 000 000				403 000
			3 000 000	695	4 000	
32	800	40 000 000				407 000

Roundly, the average yearly flood damages on the Connecticut River, as determined by this study, are $400 000. This is direct damage only and allowance for indirect losses of all kinds would double this figure, or possibly raise it to $1 000 000 yearly.

Flood protection on the Connecticut River including a system of reservoirs as well as dike or levee systems in certain of the lower cities, such as Hartford, Springfield, etc., will probably cost about $50 000 000. This would mean a yearly carrying charge of $2 500 000 to $3 000 000 for such works. It is obvious, therefore, as Mr. Uhl states, that a complete plan of flood relief on the Connecticut River is not economically justifiable based upon flood benefits alone. Other benefits from the use of reservoirs besides those of flood relief, principally from the use of water for power purposes, but also from the point of view of recreational and sanitation benefits, must bear a substantial portion of the cost of a reservoir system to justify its construction.

Mr. Wolman's statement of the factual situation in regard to flood protection is in general accord with the views of the writer.

Engineering studies of past destructive floods are generally incomplete, due to the lack in the past of effective agencies to procure and co-ordinate at or about the time of the flood the necessary information to serve as a basis for its study. Fortunately, there are some exceptions, however, as illustrated by the Ohio flood of 1913, where local agencies obtained much valuable data—particularly by the work of the Miami Conservancy District and its excellent set of engineering reports. Even in this case the data of flood damages—particularly those of an indirect nature—are uncertain. During the past decade the U. S. Geological Survey has developed a policy of procuring data of flood run-offs, following up all major floods, and is covering this field admirably.

In general, it is not likely, therefore, that much more specific data of value relating to the earlier destructive floods can be obtained, due to a dearth of definite information from the past.

The lack of detailed and carefully prepared complete programs for flood relief is quite obvious, in most sections of the United States, and little attention has been given as yet to the consideration of other water uses, in co-ordination with flood control.

As Mr. Wolman states, every major flood brings a popular clamor for action which if hastily acted upon, without careful and deliberate planning, is bound to mean wasteful and perhaps ineffective measures.

The inhibitions of the Copeland Act of 1936, which was directed solely at flood-control measures, have had an unfortunate effect in causing almost a complete lack of comprehensive planning of river developments thus far in accord with all the other aspects of river conservation and control. Moreover, in many sections of the country flood-relief benefits are not sufficient to warrant the expenditures required for this purpose alone.

Although the destructive aspects of a river in flood must be reckoned with, the development of its constructive and useful qualities prevailing most of the time should certainly not be overlooked and flood-relief measures are only a part of the general plans that should be made and consistently followed in the full development of the streams of the country.

E. D. Hendricks,[51] M. Am. Soc. C. E. (by letter).—New York State has a varied topography. Its surface drains into the Mississippi, through Chesapeake Bay, Delaware Bay, and New York Bay, into the Atlantic Ocean, Lake Erie, the Niagara River, Lake Ontario, and the St. Lawrence River. It contains the lowest divide into the great central basin between Canada and the Gulf of Mexico. The writer has been familiar with the Oswego and Mohawk drainage areas for many years, both from personal observation and from the records that have been kept since 1898, the year when the U. S. Deep Waterways survey was started across New York State from the Hudson River to Lake Ontario. This survey was followed by the New York State Barge Canal surveys and the record has been continued with a greater or less continuity until the present time.

For the ten years (1927–1937) records in the Oswego River drainage area have been kept by Foster B. Crocker, M. Am. Soc. C. E. The control of the principal tributaries of the Oswego River, namely, the Seneca, Clyde, and Oneida Rivers, is vested in the State Department of Public Works as these streams are canalized and are part of the New York State Barge Canal System.

As a result of the intense rainfall of July, 1935, and of the much greater volume of run-off that occurred in March, 1936, this drainage area was subjected to the two major floods generally described by Messrs. Harrington and Johnson.

Flood control that has been accomplished in New York State prior to the great floods of 1935 and 1936, except in isolated cases, has been incidental to other purposes. The isolated instances with which the writer is familiar are the Hornell and Canisteo flood abatement projects on the Canisteo River, which were completed before 1927 and which, in the case of the 1935 flood, proved inadequate. The Sacandaga Reservoir was as much a water-storage project for power interests as a flood-control project and a large part of its cost is being paid for by power corporations. In the writer's opinion the deepening of the Hudson River down stream from Albany, making that city a seaport, had as much effect in reducing the flood level at Albany as the Sacandaga Reservoir.

The 1936 flood was the greatest of which there is a record on the Mohawk River in respect to the rate of flow. However, it did a relatively small amount of damage compared to other floods, such as those of October, 1903, March, 1904, March, 1910, March, 1913, and March, 1914.

The floods of 1904, 1910, and 1914 were accompanied by ice gorges. The flood of 1913 on the Mohawk had climatic conditions similar to that of 1936—a period of warm weather early in March followed by high water, followed in turn by a rain in the latter part of the month on saturated or frozen soil. The physical conditions, however, were greatly changed in 1936; that is, the canalization of the Mohawk River had been completed, and a number of additional storage reservoirs were in operation on the tributaries, the level of which reservoirs had been drawn down early in March. The result was that although a greater quantity of water was retained in reservoirs on the head-waters, a smaller quantity was retained on the flood-plains of the river, resulting in an increased discharge at the mouth with much lower elevations up stream; for example, the estimated discharges, in cubic feet per second, were: 1913, 110 000, and 1936, 130 000.

---

[51] Senior Claims Engr., State Dept. of Public Works, Albany, N. Y.

Neither the reservoirs on the Mohawk nor the canalization were for the purpose of flood control. However, nearly all flood damage has been eliminated between Schenectady and Utica, a distance of 80 miles, where prior to the canalization the ground floors of property located within the flood-plain were flooded every few years.

Although the primary purpose of the control of the Seneca and Oneida Rivers was to render them navigable with a minimum depth of 12 ft, an indirect benefit has been to reduce flood elevations and to reclaim large tracts of land, particularly in the Montezuma marshes through which the Seneca River flows. The property owners along these streams, however, have had a different opinion; and as a result have filed claims against the State alleging that as a result of the canalization of the aforementioned streams and their control by the State, flood conditions have been aggravated with increased damage to them. Test cases have been tried in the New York State Court of Claims for the years 1935 and 1936, and in the preparation of the State's defense a great mass of data concerning previous floods has been collected, together with an intensive study of climatic conditions, rate of inflow, progress of the flood, yield of the tributary streams, etc.

The drainage area of the Oswego River is shown on Fig. 11. It consists of 5 120 sq miles at Oswego. A daily discharge record is kept by the U. S. Geological Survey at that place. The State maintains a discharge station at Fulton, 11 miles up stream (area, 5 017 sq miles). At Three Rivers, 23 miles up stream from Oswego, the Oneida (area, 1 493 sq miles) and Seneca (area, 3 445 sq miles) Rivers unite to form the Oswego.

The State maintains a gaging station at the Caudenoy Dam, 12 miles up the canalized Oneida River, where the drainage area is 1 377 sq miles. This dam maintains the water surface in Oneida Lake, 4 miles farther up stream, and is provided with a flood-gate which, with a guard-gate above Lock 23, permits the lowering of the water surface in the lake during the winter months and the control of the outflow from the lake.

Seneca River has its first dam at Baldwinsville, 12 miles up stream from Three Rivers. This dam is supplied with a 30-ft flood-gate. Nine miles up stream from Baldwinsville, the State has a gaging station consisting of two recording gages situated at each end of a 4 300-ft rock-cut channel, known as State Ditch. The discharge from the drainage area of 3 073 sq miles is computed by the slope-area method. Thirty miles up stream is the junction with the Cayuga-Seneca Canal. The main canal proceeds westerly up the Clyde River, and 6 miles farther up stream the State maintains a gaging station at Clyde, which has a drainage area of 880 sq miles. Thirty miles farther up the Clyde, at Lock 30 at Macedon and the westerly limit of the water-shed, the water brought into the drainage area from Lake Erie and Genesee River is measured through calibrated sluice-gates. This quantity averages about 135 cu ft per sec during the navigation season, April to November, inclusive. It varies between 100 cu ft per sec and 170 cu ft per sec, depending on the number of lockages at Pittsford, 17 miles west of Macedon.

Returning to the main channel of the Seneca River: The Cayuga-Seneca Canal proceeds up the Seneca River southerly a distance of 4 miles to the outlet of Cayuga Lake, the surface of which is controlled by six Tainter gates. The outflow through these gates has been calibrated and a daily record is kept. The drainage area above this station is 1 572 sq miles. The canal turns westerly from Cayuga Lake, following the course of the Seneca River to Waterloo, a distance of 8 miles, where the control works regulating the surface of Seneca Lake are maintained and where a daily record of the outflow from the lake is kept. The drainage area above Waterloo is 749 sq. miles.

In addition to these gaging stations maintained by the State the U. S. Geological Survey, under the supervision of Mr. Harrington, as District Engineer, maintains three stations on the Oswego River water-shed, all of which are near the head-waters, in addition to the one at Oswego at the outlet of the drainage area (see Table 12).

TABLE 12.—GAGING STATIONS MAINTAINED BY THE UNITED STATES GEOLOGICAL SURVEY

Station		Drainage Area	
At (1)	On (2)	Name (3)	Area, in square miles (4)
Taberg, N. Y.	The East Branch of Fish Creek	Oneida River	189
Auburn, N. Y.	The outlet of Owasco Lake	Seneca River	208
Ithaca, N. Y.	Fall Creek	Cayuga Lake	124

Storm of July, 1935.—The writer is convinced, from personal observations and Court testimony, that the storm of July 7 and 8, 1935, was more extensive than is shown by Fig. 12[52], which is based on reports from rainfall stations of the U. S. Weather Bureau. In the writer's opinion, the precipitation was concentrated at or near the higher elevations where there are no Weather Bureau stations, and passed over the low divides or valleys with a heavy precipitation to concentrate with double the precipitation on the hills beyond; that is, extending from the New York-Vermont line east of Mt. McGregor, the area of high precipitation extended westward along the southern escarpment of the Adirondacks to Stewart's Landing, 20 miles northwest of Gloversville. South of the Mohawk the storm concentrated on the peaks of the Cherry Valley Hills, on the Mohawk-Susquehanna divide, and Oak Hill, which is the divide between the Mohawk and the Schoharie Rivers. Thus, streams entering the Mohawk from the south and west of the Schoharie, show peak flows of more than 400 cu ft per sec per sq mile which resulted from a rainfall of not more than 6 hr duration.

---

[52] *Water Supply Paper 773-E*, U. S. Geological Survey.

However, the water-shed of the Oswego River is well supplied with rainfall stations in addition to the U. S. Weather Bureau stations, most of which are maintained by the New York State Department of Public Works and by the Oswego River Watershed Corporation. In addition to precipitation records, snow survey records are kept.

The run-off that resulted from the rainfall of July 7 and 8, 1935, does not appear to have been equalled for summer flows on the Seneca River in the period in which records have been kept—that is, for 37 yr. Fortunately, no unusual run-off occurred on the water-sheds of the Oneida and the Clyde Rivers. The precipitation on the Oneida water-shed was less than one-half that on the Upper Seneca and the precipitation on the Clyde water-shed was no more than that from an ordinary summer storm. In fact, at least one-third of the area draining into Cayuga and Seneca Lakes did not experience a really destructive rain.

The remainder of the Cayuga and Seneca Lake areas had a rainfall that resulted in an inflow at the rate of 80 000 cu ft per sec for 8 hr on Seneca Lake, from a drainage area of 749 sq miles. Cayuga Lake had a rate of inflow of 100 000 cu ft per sec for 8 hr from a drainage area of 823 sq miles. Due to the storage utilized in both lakes, the peak outflow from Seneca Lake was 4 400 cu ft per sec and that from Cayuga Lake was 16 000 cu ft per sec. The elevation reached in Cayuga Lake was 386.0 and in Seneca Lake, 449.34. The peak discharge at Baldwinsville was 12 000 cu ft per sec. The greatest damage on the navigable waters resulted to truck gardeners cultivating thousands of acres of muck land in the former Montezuma marshes which had been rendered tillable by the canalization of the Seneca River between Cayuga Lake and Jack's Reef.

Greater damage occurred on the streams flowing into the lakes and has been described elsewhere by Mr. Johnson.[52] Over these streams the New York State Department of Public Works exercises no control.

The discharge at Jack's Reef or at Baldwinsville had been exceeded a number of times in the late fall or spring months, both before and since 1918, the date of completion of the Barge Canal There is no record of a greater summer run-off. The summer elevation in Cayuga Lake had been exceeded several times prior to canalization, but with an outflow of less than 4 000 cu ft per sec. In August, 1922, the lake reached an elevation of 386.1; and although that was a summer of heavy precipitation, the high water was as much the result of the method of operation as of the climatic conditions. Any elevation in excess of 385.0 results in damage to property surrounding the lake and particularly to property in Ithaca at the head of the lake.

The term, "method of operation," is used advisedly. In 1922, the control of the navigable waters of the State were under a bureau separate from the State Engineer Department. Since 1927 both the Division of Canals and Division of Engineering have been included in the Department of Public Works under Frederick Stuart Greene, M. Am. Soc. C. E., as Superintendent. Not only has there been an increase of accurate records kept by Mr. Crocker; but the long-continued sequence of the records has resulted in a sound engineering basis on which a proper method of operation has been predicated.

Flood of March, 1936; Oswego River Water-Shed.—The climatic conditions causing the flood of March, 1936, seem to have been similar in many respects to those that occurred in March, 1865, as shown by the report[63] of J. P. Goodsell, Division Engineer of the Middle Division, New York State Canals, including the Erie, Oswego, Cayuga, and Seneca Canals and the Oneida River improvement. Mr. Goodsell reported that the measured flow at Jack's Reef was 19 435 cu ft per sec on March 22, 1865, and that this was the greatest flow ever experienced in the Seneca River. The greatest flow preceding this was in March, 1857, when the discharge at Jack's Reef was 15 269 cu ft per sec.

There was another great flood on April 10 and 11, 1873, in which Cayuga Lake reached the same elevation as was reached in 1865, but no discharge measurements were reported. The peak discharge at Oswego for the 1865 flood has been estimated as 42 000 cu ft per sec. The peak discharge at Phoenix has been stated (Empire Street Railway Company *vs* the State of New York) as 30 000 to 35 000 cu ft per sec. The Town of Phoenix is below the junction of the Oneida and Seneca Rivers and has a drainage area of 4 940 sq miles, about 500 sq miles greater than at the gaging stations on the Seneca and Oneida Rivers.

The peak discharge at Phoenix is usually about equal to that at Oswego. However, in the 1865 flood, 170 ft of a dam situated on the river 4 miles up stream from Oswego, was washed out which could well account for the difference of 7 000 cu ft per sec. The highest flood elevation recorded in Oneida Lake prior to the construction of the Barge Canal was 376.0, with an estimated peak outflow of 12 500 cu ft per sec. This peak probably occurred in the flood of 1865 and checks very well with the peak at Phoenix and the discharge from the Seneca River, at Jack's Reef. The effect of the control, incidental though it was, is disclosed in Table 13. The low navigable stage of Cayuga Lake is 381.5 and that of Oneida Lake is 369.9. During the winter of 1936 the level of Cayuga Lake was drawn down to 380.3 and that of Oneida Lake to 368.5, in preparation for the

TABLE 13.—COMPARISON OF ELEVATIONS AND DISCHARGES, FLOODS OF 1865 AND 1936

Date	Cayuga Lake elevation, in feet above sea level	Seneca River discharge, in cubic feet per second	Oneida Lake elevation, in feet above sea level	Oneida River discharge, in cubic feet per second	Oswego River discharge, in cubic feet per second
1865..........	389.3	19 435	376.0	12 500	35 000
1936..........	386.7	22 500	375.0	11 700	37 000

---

[63] Annual Rept., State Engr. and Surv., January 23, 1866.

expected high water that did occur. Damage did result from high water in the Oswego River drainage area, and claims have been filed against the State, but it is anticipated that they will be dismissed.

Messrs. Harrington and Johnson call attention to the importance of basic data depending on long-continued records. This discussion is primarily for the purpose of illustrating the value of numerous long-continued records and their intelligent use by a skillful engineer. The reduction of a flood elevation by 1 ft or 2.5 ft may appear negligible in sections where flood rises greatly exceed those in New York State; but this lowering reduced by hundreds of thousands of dollars the damage suffered. The streams discussed traverse regions of long settled and thickly populated communities and the last foot of rise usually causes the maximum damage.

To spend great sums on construction without the help of basic data is to insure not only waste, but greater injury than the benefits realized.

The reference by Messrs. Harrington and Johnson to the importance of considering the engineering economics of each problem is often lost sight of by some enthusiastic advocates of only one phase of the problem of flood control. Thus, there are the reforestry proponents claiming deforestation to be the primary cause of floods. This cannot be true of the discharge areas discussed herein. There is a greater forest cover now than there was in 1910 (from the writer's personal observation). The 1935 Graphic Compendium of the New York State Planning Board indicates that lumbering reached its peak in New York State in 1869, and that there has been a great reduction in improved farm areas since 1875. Man-made changes, apparently, have relatively little or no effect in these two instances compared to climatic disturbances over which Man has no control and no definite knowledge of the cause.

EDWARD W. BUSH,[54] M. AM. SOC. C. E. (by letter).—Combined flood control and hydro-electric developments are engineering subjects that will keenly interest the profession for some time to come. The papers of this Symposium are very valuable contributions on the subject. Many schemes are under consideration for building groups of reservoirs for the dual purpose of flood control and electric development, but practically no information has been presented by their proponents as to the procedures that necessarily must be followed by those operating such dual systems so that the flood-control protection will receive proper safeguarding and, at the same time, those relying on the generated electricity will be satisfied with the services obtained.

In the few cases where procedures have been briefly mentioned the proponents have stated, what to them seems obvious, that the reservoirs will be drawn down just before the freshet seasons arrive and after they are filled by the freshets the impounded waters will later be used to generate electricity. This is quite a simple solution if the rain storms and the weather could be foretold accurately, or could be regulated, but seemingly quite fantastic when the actual facts are recognized. Those wanting protection against flood damages need the reservoirs empty except when in use for holding back flood waters, and when so filled they should be drawn down as soon as the outflow would not cause damage so they are set ready for the next freshet when it comes. Those using the electricity and those selling it to obtain funds for retiring the cost in whole or in part of the reservoirs will desire plenty of water in the reservoirs at all times. It would seem that these conflicting interests cannot be reconciled.

---

[54] Engr., Aetna Casualty and Surety Co., Hartford, Conn.

The Connecticut River well illustrates the uncertainty of the time of high freshets. During the past 300 yr, the highest freshet came in the middle of March, 1936, the next highest freshet came in the first week of May, 1854, and the next highest came in the first week of November, 1927, at a time when very low water has often occurred in past years. Fairly high freshets have occurred at one time or another in about every month of the year.

It is highly improbable that any official or board of officials in charge of the operation of a system of reservoirs constructed for a dual purpose could at any critical time determine in advance whether or not to empty the system, or to keep it filled or partly filled if it happened to be in that condition. At such a time the power users and sellers could readily estimate the dollar value to them of any stored water and would strongly urge their claims for such, but those relying on the reservoirs for the protection against flood damages would probably not be organized and, therefore, not able to present forcefully their advantage from having empty reservoirs when what might be termed, "border line" situations arose; and any freshet, when it reached its crest, might only be one of moderate size.

After several of such false alarms it is expecting too much of human nature to believe that those in control would operate a system so that the flood prevention side would always receive the full protection needed. This seems to be a fundamental consideration that should not be lost sight of. In most of the cases when a critical situation is forming there will not be time to convene a board of consulting experts to determine whether or not the reservoir gates should be opened or closed, and even if convened the experts would probably not know the correct answers.

IVAN E. HOUK,[55] M. AM. SOC. C. E. (by letter).—Comprehensive treatments of flood-control problems presented in this Symposium show that the disastrous flood occurrences of recent years are gradually causing the development of a long needed, national, flood-prevention movement. Some of the Federal plans outlined by Colonel Covell may be delayed for many years, possibly until future flood calamities provide new impetus. Nevertheless, if only a few are carried to completion at this time, they will result in saving of life and property which can scarcely be evaluated on a purely monetary basis.

---

[55] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

Probably one of the most urgent needs in connection with present flood-control work is an adequate forecasting system. Officials of the U. S. Weather Bureau have rendered excellent service on some of the larger rivers where appreciable time intervenes between the occurrence of storm rainfall and the arrival of flood peaks. However, much remains to be accomplished in developing adequate forecasting organizations for small tributary streams in the upper parts of the drainage areas where maximum flood stages occur only a few hours, or only one day or two days, after the most intense precipitation.

The requirements for an ideal river and flood service mentioned by the late Mr. Hayes,[56] if provided in sufficient number in each river section, should furnish the necessary facilities for forecasting maximum stages during most flood-producing storms. Naturally, they would not be adequate for forecasting cloudburst floods in isolated mountainous drainage courses, where crest stages arrive almost simultaneously with the first run-off (as at Heppner, Ore., on June 14, 1903, when two hundred people were drowned, one-third the town washed away, and approximately $250 000 worth of property destroyed).

Cloudburst floods of the Heppner type occur so suddenly and erratically that their prediction probably never will be practicable. In such cases residents along the lower sections of the streams usually must depend on telephone warnings from up-stream locations. During the Cherry Creek flood of August 3, 1933, caused by cloudbursts south of Denver, Colo., and the resulting failure of the Castlewood Dam, telephone and radio warnings were so effective that only two lives were lost.[57] Probably the only way to insure warnings of advancing cloudburst floods, if such warnings should ever be considered necessary, would be to install automatic float-gages at up-stream locations, and to connect them electrically with the forecasting office, so that alarms would be sounded when dangerous stages were reached.

Automatic recording river and rainfall gages are desirable for use in forecasting floods in small up-stream drainage areas. However, they are not essential. About 1917 the writer was forecasting floods in the Miami Valley of Southwestern Ohio, where the most remote parts of the watershed were not more than a hundred miles from the Central Office. Cooperative arrangements were made with the Weather Bureau observers whereby each inch of rainfall and each foot of river rise were reported by telephone or telegraph during storm periods. The observers were paid additional compensation on the basis of the number of special reports submitted. Consequently, they watched their gages and made their reports promptly. The system worked so satisfactorily that accurate forecasts of river heights could be issued well in advance of the arrival of the crest stages, not only for the principal cities of the Valley, but also for the various construction activities which were being carried on by the Miami Conservancy District.

---

[56] Mr. Hayes died November 16, 1936.

[57] "Failure of Castlewood Rock-Fill Dam", by Ivan E. Houk, *Western Construction News*, September, 1933, pp. 373 to 375.

The real value of installing recording rainfall and river gages in forecasting systems for small drainage areas lies in the satisfactory data they supply for subsequent detailed studies of hydrologic conditions. The forecasters will want to make such studies after the floods have passed, when they have time to analyze all factors carefully. During the occurrence of the storm rainfall and the arrival of the flood stages they will be too busy to make detailed quantitative analyses of run-off phenomena. At such times, the most important matter is to get the necessary rainfall and run-off reports, promptly, so that forecasts can be quickly formulated and issued in time to be of value. Consequently, telephone, telegraph, or radio transmission facilities must be available.

Mr. Hayes mentioned the desirability of conducting snow surveys in the Eastern mountains. The methods to be used in such surveys probably should be somewhat different from those used in Western United States, since the information will be used in forecasting flood-stages during the winter and spring months instead of total run-off during the spring and summer seasons. Probably the accurate measurement of the water content of the snow at selected stations throughout the eastern drainage areas will be more satisfactory for flood-forecasting work than the establishment of snow courses such as are used in the West. Measurements of the water content should also be made much more frequently than snow surveys are usually conducted.

JOHN E. FIELD,[58] M. AM. SOC. C. E. (by letter).—In proposing five changes in the present plan of operating the U. S. Weather Bureau, the late Mr. Hayes listed snow surveys as Requirement (*c*). The method of making snow surveys proposed herein applies only to those areas where the snow banks last well into the summer and where the spring floods come from melting snows and are probably confined to the Rocky Mountains, and the Wasatch and Coastal Ranges. Even limited to those areas snow water affects the territory from the 104th Meridian, about the eastern boundary of Montana, Wyoming, Colorado, and New Mexico, to the Pacific Ocean, and especially to those areas where irrigation is practical.

In the building of the hydraulic-fill dam of the Terrace Reservoir, in the Alamosa River, in Southern Colorado, covering the years 1908 to 1912, it was necessary to know the probable run-off of the river a week or more in advance, to be able to estimate the probable peak flow from melting snow, and to know when the maximum had passed, because any quantity greater than 1 200 cu ft (the capacity of the outlet turned) must be stored or carried over the dam by flumes. By observing the snow banks, about 10 miles distant, in the canyons and gulches, or in the high mountains of the water-shed (10 000 to 12 000 ft above sea level), the writer found several that were indicative of the run-off to be expected in the days immediately following the observations. The weather conditions, of course, were taken into account in forecasting the run-off for each day as cloudy weather lessened the melting and clear days augmented it.

---

[58] Cons. Engr., Denver, Colo.

At the end of four years and with the records of the flow of the river, the writer felt he could predict the season's run-off quite satisfactorily, from the appearance of the snow banks in May.

Being called upon to estimate the probable supply for the City of Denver, Colo., in March, 1933, and the predictions later proving to be much in error, it occurred to the writer that a study each spring of the snow banks on the city water-shed would furnish a more reliable basis for prediction than precipitation, snow surveys, and soil moisture records, which had been used in the 1933 estimates.

The Denver Board of Water Commissioners was induced to test the theory; it furnished telescopic lenses for the cameras and designated Harry L. Potts, M. Am. Soc. C. E., to gather the data. A program was devised (since much improved by Mr. Potts) fixing the points from which photographs were to be taken, at least once each month, and then co-ordinated with stream flow and weather records.

These records are depended upon by the Board of Water Commissioners of the City of Denver, in the operation of the city system and particularly in determining whether the City can safely sell stored water to proprietors of the irrigation canals below, who are in great need of water in July and August.

It is the hope of the writer that the current research will show the method to be both simple and reliable and, supplemented by some snow measurements, will be valuable to all who are concerned with water from the high mountain areas. It is his wish that some Federal Department will adopt the method and that it will lead in time to the publication monthly of the probable run-off on each stream, in a manner similar to the crop reports now being furnished by the Government to the public.

C. S. Jarvis,[59] M. Am. Soc. C. E. (by letter).—It is indeed gratifying to note the progress achieved recently toward recognizing and sponsoring flood control, stream regulation, and water utilization as both national and local problems. It has long represented "a consummation devoutly to be wished", and earnestly sought by leaders in the Engineering Profession, by far-sighted and progressive economists, legislators, and community officials. Now that such generous provision has been made for the flood control problems in several regions of the United States, it is desirable to continue such activities until equitable distribution has been accomplished among the several States.

It has long been advocated, although occasionally challenged by those reluctant to "fall into line," that all storage development under intelligent operation should result in positive, measurable benefits to flood control and stream regulation. Notable confirmation is accorded in a recent paper by Eric Chester Hillman, with discussions, entitled "The Effect of Flood

---

[59] Cons. and Hydr. Engr., SCS, Washington, D. C.

Relief Works on Flood Levels Below Such Works".[60] Among the conclusions[61] is the following: "The effect of eliminating storage capacity will be to accelerate the flood wave and increase the flood peak below the area from which the floods have been excluded."

In the case of the Nottingham flood protection plan, the reduction of about 10 000 acre-ft of flood-plain storage, due to new protecting levees, resulted in speeding up the flood crest by 7 hr, and a rise of 0.4 ft during a freshet, with maximum flow of 20 000 cu ft per sec. Obviously, increase of storage, therefore, would retard and reduce flood crests proportionately.

Conversely, the Bon Accord Dam,[62] impounding 400 000 000 cu ft (9 183 acre-ft) at full supply level, with a surface area of 614 acres and maximum storage depth of 45 ft at the spillway level, reduced a maximum inflow of 16 000 cu ft per sec to a regulated outflow not exceedingly 10 500 cu ft per sec for the maximum observed flood from 121 sq miles, including Pretoria, South Africa.

Even if, in an extreme case, a reservoir may be full or nearly full to spillway level at the arrival of a flood crest, there is generally considerable regulation available due to storage capacity above the spillway crest, together with back-water effects along contributing stream channels. Ordinarily, intelligent operation of storage reservoirs will provide nearly maximum regulation during the critical seasons, and satisfactory flood routing in the lower courses.

JOSEPH JACOBS,[63] M. AM. SOC. C. E. (by letter).—Every member of the Society who feels a concern in Federal flood-control activities and policies must have read this highly informative Symposium, with great interest and appreciation. Because of the persistent, and not infrequently unnecessary, encroachment of the works of Man upon the flood planes of the rivers of the United States, and because of the increased property values attaching to urban, suburban, and rural developments along its streams, floods are a steadily growing menace and, year by year, are becoming a more serious economic problem both nationally and locally. The writer has always felt a deep interest in the matter and, abstracting largely from material which, from time to time in the past, he has prepared on the subject, he submits the following as an expression of his views concerning a proper approach to the problem of a permanent Federal policy in respect of flood control.

In the discussion of flood control there is frequent reference to the so-called 308 Reports, prepared under direction of the Corps of Engineers, U. S. Army, and it is not an uncommon view, even among engineers, that these reports provide all the preliminary information needed concerning American rivers and that they constitute an adequate basis for the formulation of a national flood-control policy. Commendable as was the undertaking, and excellent as was its execution, it is believed that the 308 Reports were by no means exhaustive finalities as to the matters with which they dealt; nor were they adequately inclusive territorially. This is particularly true as to flood control which apparently received far less consideration than did the navigation, power, and irrigation phases of the reports. No one familiar with the matter, and least of all, the Army engineers, will contend that the reports were in any sense final. Neither sufficient funds nor sufficient time was available to cover the country fully. Necessarily, there were many streams that must have been only cursorily investigated and many others, no doubt, that were not then, and have not yet been, investigated at all. It is believed, too, that the 308 investigations were not directed toward the specific problem of a permanent Federal policy as to flood control but dealt rather with the engineering aspects of individual projects. There is yet much important investigational work that ought to be done before any final Federal policy should be formulated in detail.

During the next thirty or forty years probably as much as $2 000 000 000 will be expended on flood-control works and, unquestionably, a large part of this expenditure will devolve upon the Federal Government. Certainly, an activity of that potential magnitude is worthy of the most careful consideration by the responsible agencies, in order that sound technical and legislative policies respecting it may be established and that maximum economy and facility in planning, in execution, and in final operation of the completed works, may be achieved. The evolvement of these governing policies should be based upon definite knowledge of what the flood-control problem is in all its major requirements and ramifications, and when the necessary surveys have been made and the factual data assembled they should be interpreted, in their broad economic aspect, by men technically competent for such a task.

Congress, under the Commerce Clause of the Constitution, assumes jurisdiction over the navigable waters of the United States and generously provides for navigation requirements. To the extent that floods have affected navigation the Government has regarded them as being "affected with a Federal interest" and has made appropriations therefor on that basis. As to floods on non-navigable streams, these, in general, have been regarded as lacking in "Federal interest" and, therefore, have not been considered a matter of Federal concern or responsibility. The Federal Government seems now to recognize that it must retreat from the negative policy that heretofore has characterized its attitude toward flood control and assume a larger responsibility concerning it. This salutary change of attitude is manifest in the Flood Control Act of 1936 and, although the general flood-control measure of 1937 failed of final enactment, 'the new Federal purpose of a larger responsibility in flood-control matters was also manifest in that measure. The entire subject of flood control is now in a state of flux, and it needs sane guidance toward a policy not temporary or ephemeral, not based on hasty considerations, but one that is sound and enduring because it is based upon a thorough-going investigation of all phases of the problem. No such thorough investigation has yet been made.

The chief significance of the Flood Control Act of 1936 is not so much in its detailed provisions, some of which are deemed open to question, nor in its project authorizations, but rather in the incidence of a new Federal attitude toward flood control. It is the writer's feeling that some of the provisions of the Act are not well considered. It appears to him that the measure must have been rather hastily drawn, probably with greater consideration for providing early unemployment relief than with a view to formulating a definite, Federal flood-control policy. Those provisions of the 1936 Act, the desirability of which the writer questions, are as follows:

(*a*) It authorizes the appropriation of $310 000 000 for the construction of a very large number of specifically designated projects. It is seriously doubted whether there could have been sufficient investigation to warrant a Congressional approval of the large number of projects involved in this authorization. Presumably, the projects are subject to further investigation and presumably, too, for those that are finally found to lack merit, the actual appropriation will not be made; but is such wholesale approval in advance of final investigation a desirable Congressional procedure? The writer thinks not.

(*b*) It provides that the local agency concerned shall, up to 50% of the total project cost, furnish all required lands and rights of way. The usual defense of this provision is that it will result in lesser right-of-way costs, but that need not be the case if the local agency is required to pay its full and fair share of all project costs, whatever they may be. Rights of way constitute as legitimate a part of a project as do its structural elements, and its cost should not be treated as a thing apart but should be included with other costs without distinction. The inconsistency of the present provision is obvious when one realizes that right-of-way costs may easily range from practically nothing to more than one-half of the total project cost and they cannot, therefore, except by accident, be a fair measure of that portion of the total cost that should be borne by the local agencies. There are many projects for which the local agencies should bear the major part of the total cost and others for which they should bear practically none of the cost, and these facts should be recognized in making cost allocations. An instance is recalled of a $2 500 000 projected Federal institution whose location was largely predicated on a free furnishing of the land required for its accommodation, land that could cost scarcely more than 3% of the total project cost, and the communities of three States were asked to submit offers. How impractical and archaic it is to determine the location of an important Federal enterprise on such a basis! It is to be hoped that the Federal Government will avoid making such a procedure part of its flood-control policy.

(*c*) It provides that the local agencies shall hold the United States free from damages due to the construction works and that they shall maintain and operate all the works after completion. Why should these onerous responsibilities necessarily be imposed upon the local agencies? It seems to the writer that the allocation of these responsibilities and their costs, as well as the allocation of initial construction costs, should be predicated on the theory of conferred benefits. If the Federal interest in a project is dominant, as it might easily be on a navigable stream, or if the project is of an interstate or international character, as some of them will be, then it would seem most practical for the Federal Government to operate; but this does not necessarily mean that the Federal Government should bear all the costs of operation. Other conditions may clearly indicate that operation should be by the local agency and a final flood-control policy should contemplate and provide for these variable contingencies.

As stated previously, the writer thinks that there is much investigational work yet to be done before a final flood-control policy should be fixed. There are deficiencies in factual information and there are differences in judgment as to the best Federal policy respecting flood control. These deficiencies cannot be supplied, these differences cannot be composed, and the best final policy cannot be determined, without additional facts developed from actual further surveys and investigations. It is suggested, therefore, that the Federal Government ought now to undertake a comprehensive, nation-wide, flood-control survey and investigation, and that the formulation of a final flood-control policy should await the results of that investigation. Some of the factual material that such an investigation should provide, and some of the questions it will have to deal with, are embraced in the following items:

(1) Sufficient basic data to afford a broad-gage perspective of the entire problem including, for all important drainage basins and for the country as a whole, the extent of the flood menace, the average annual losses due to floods, an outline of the character of corrective measures that will need to be applied, and something of an estimate as to the probable gross initial and gross annual cost of these corrective measures.

(2) A careful assembly of all dependable data as to actual flood losses. The validity of flood-control economics is so closely related to a correct evaluation of this factor that a special effort should be made to secure authentic information concerning it. Many wholly unreliable estimates of flood-control losses are extant, both above and below their true value.

(3) An appraisal of the causes of the present unpreparedness for major floods. To what extent is a deficiency of hydrologic data a contributing cause and to what extent is there a failure adequately to heed the warnings afforded by the data already available? To what extent is there unwarranted encroachment, beyond real economic requirements, on the natural flood planes of American rivers? To what extent is there a lack of adequate legislation, both Federal and State, and a lack of an adequate plan of finance, to make possible the construction and operation of needed flood-control works?

(4) What principles should govern in framing a Federal flood-control law? Should such a law provide for, and require, the co-operation of local agencies and provide for an allocation of cost on the basis of benefits conferred and, if so, should this allocation apply only to construction cost, or should it apply also to the initial investigation cost and to the cost of operation and maintenance? Should not the law be devised to serve either a single or a multiple political jurisdiction; that is, should it not be sufficiently flexible to permit the construction of works for a restricted area or for an entire drainage basin that may extend beyond the boundaries of a single county or a single State, or even beyond a national boundary as might be the case for international streams?

(5) What is the best basis for a rational and equitable appraisal of benefits to Federal and local agencies resulting from the construction of flood-control works? This is not a simple matter but, no doubt, some general principles can be evolved that will facilitate solution for each particular case.

(6) What agency should maintain and operate the flood-control works and what principles should control in determining this question?

(7) Should there be State legislation permitting a requirement, by the State, that certain storage capacities be reserved for flood-control purposes in any new storage reservoirs that may be built, the extra expense entailed thereby to be borne by the beneficiaries concerned?

Doubtless there are other pertinent items that could be added but the foregoing list is sufficiently extensive to indicate that there is a considerable body of factual data and material to be acquired, and that the proposed comprehensive investigation is truly an important and necessary preliminary for the best formulation of a final flood-control policy. It is the writer's judgment that the cost of such an investigation will approximate $25 000 000 and that a time interval of five years may be required for its completion. It should be emphasized, however, that the prosecution of this work need not in any way embarrass or delay the construction of individual projects that may require earlier attention, but the legislation authorizing them should not be regarded as representing any final Federal flood-control policy.

What provision should be made for prosecuting the proposed investigation? An interpretation of the data provided by the investigation, and the translation of such data into a sound, Federal flood-control policy, will require not only a high order of technical skill and understanding but, equally so, a high order of statesmanship. It is suggested that there be created a Federal Flood Control Commission whose duty it shall be to direct the investigation, and to render a report of its findings, which shall include a specific recommendation as to a definite Federal policy respecting flood control. The personnel of such a Commission should include representatives of those few Federal agencies that now have a major interest in flood control, and it should also include men from the outside who, by training and experience, have special qualifications for such an inquiry. It is the writer's belief that such a comprehensive investigational program as here proposed would, in material degree, receive the financial, co-operative aid of the States.

W. M. Dawley,[64] M. Am. Soc. C. E. (by letter).—Under the heading, "Projects in the Ohio Basin," Colonel Covell refers to flood-stages in the Ohio River that attained a gage height of 70 ft (prior to January, 1937), with consequent damage due to the flooding of basements and the lower floors of buildings. There is an Indian tradition of a much higher flood at Cincinnati which, if repeated, would inundate the entire business section of the city, with consequent damages far in excess of those due to the 1937 flood.

In the fall of 1789, Gen. Josiah Harmar sent Maj. John Doughty with a body of troops, and discretionary power, to locate a fort in the Miami country. As a result Fort Washington was built between Third and Fourth Streets produced east of Eastern Row (later Broadway) in Cincinnati, Ohio. Some friendly native Shawnee Indians advised against the location chosen for the site for the fort, stating that it had been flooded by the Ohio River, and designated a point on the hillside to which the waters had risen, which point was at an elevation of 105 ft above the low-water mark.

Since the Indians then were a migratory people, it is not probable that a knowledge of the location of this specific high-water mark would be handed down for more than one or two generations, so this flood must have occurred in the latter part of the Eighteenth Century, possibly coinciding with the high water referred to in the press comments on the 1936 flood in the Allegheny River as being the highest of record, except that of 1763. It occurred at a time when the entire drainage area was wooded and uncultivated.

This information was gleaned before 1900 from the papers and personal correspondence of Col. Richard C. Anderson, Principal Surveyor of the Virginia Military District, in Ohio, which were then in the possession of the Rev. R. G. Lewis, of Chillicothe, Ohio. The documentary evidence is not at the moment available, but if it can be verified, it would seem that regulatory measures now proposed would have to be revised.

Howard M. Turner,[65] M. Am. Soc. C. E. (by letter).—A comprehensive description and general discussion of the 1936 flood is presented in Mr. Uhl's admirable paper. The immediate cause of this great flood in most of the New England States was the storm of March 17 to 19, the run-off from which was superimposed on a very large underlying flow due to melting snow and the run-off from the previous storm of March 12 and 13. A consideration of this particular storm and run-off is thus of interest in analyzing the flood.

The writer questions whether the high rainfall in the second storm (March 17 to 19) covered as large an area as is shown in Fig. 5. The rainfall on the summit of Mt. Washington for these three days was 5 in.

---

[64] Engr., Land and Tax Dept., Erie R. R., Cleveland, Ohio.

[65] Cons. Engr., Boston, Mass.

and not 8 to 9 in. Any such rainfall as that shown in Fig. 5 would have produced very high flows in the streams draining Mt. Washington to the west. The flow of the Ammonoosuc River, however, was only 56% of that in the 1927 flood. The pattern of isohyetal lines was probably more like that shown for the previous storm and that of 1927. It is even quite possible that the 10-in. rainfall may have covered only a very small area, and the area covered by 8 in., given as 300 sq miles, may have been only a fraction of this, as indicated by the lower rainfall at Randolph, N. H. It would be of great value if a rain-gage at an altitude similar to that at Pinkham Notch could be established on the west side of the Mt. Washington range.

In Fig. 2, showing the rainfall-area relation for several great flood-producing storms in New England, the total rainfall for 13 days in the 1936 storm is compared to other storms of much shorter duration. Considering the storm of March 17 to 19 by itself, it is interesting to note that a plotting of this 3-day storm on the rainfall-area relation chart shows it to be much less than that of the other great storms.

Figures of the total run-off for the entire two-week period of high water from March 12 through March 25 show the enormous quantity of water that flowed down the rivers. The run-off of the concentrated flow during the second peak is also of interest. The writer has made an analysis of this concentrated flood on certain rivers according to the method advanced in the report of the Committee on Floods of the Boston Society of Civil Engineers.[66] This report presented the general theory that the length of the base of the flood hydrograph at a given station for the run-off of a storm within the "concentration period" for that station was constant regardless of the size of the flood, the peak flow thus being proportional to the total flood run-off. Thus, each point on a river has its own flood hydrograph curve which is a measure of its flood characteristics. By this method of analysis the total run-off during a flood is divided into two parts, the "base flow" which is not dependent on the storm rainfall producing the flood, and the "flood run-off" due to the storm rainfall within the concentration period of the basin. From this flood run-off "flood characteristic curves" were developed. These curves were determined from the hydrograph of the flood run-off above the base flow set on a unit basis by dividing the time and quantity of the flow by the square root of the drainage area, and the quantity of flow, in addition, by the number of inches of flood run-off, thus giving a flood hydrograph reduced to a 1-in. flood run-off from 1 sq mile of drainage area. This "flood characteristic curve" is somewhat similar to the "distribution graphs" of the unit hydrograph method of analysis developed by L. K. Sherman,[67] M. Am. Soc. C. E., which express the shape of the flood hydrograph above the base flow in terms of percentage of peak flood run-off, instead of in terms of flow for a 1-in. run-off, and of the actual time instead of time reduced to a unit basis. The base flow is also computed differently, but in cases that the writer has analyzed by both methods the difference is small, and the two curves are very similar.

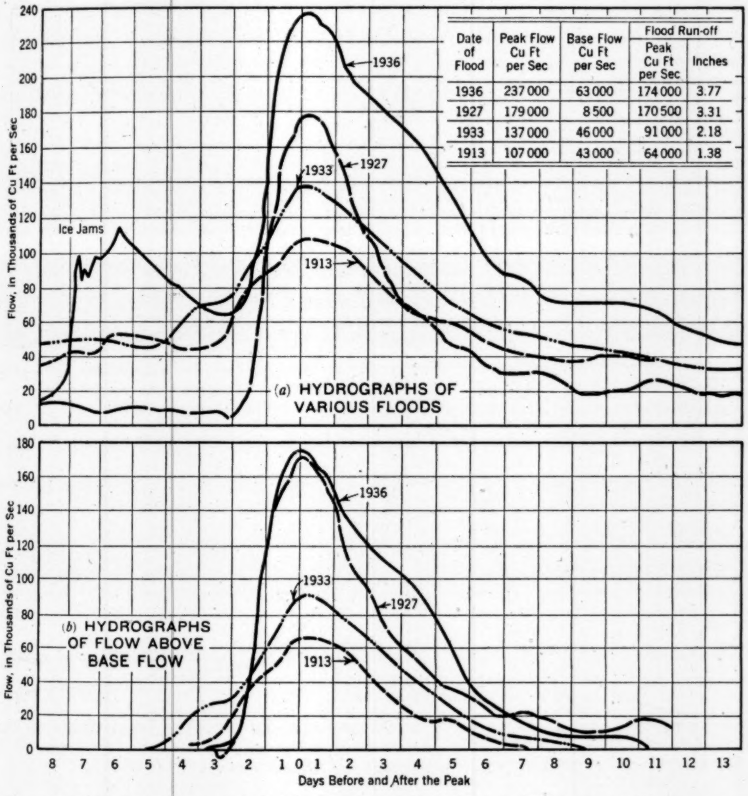
[66] *Journal*, Boston Soc. of Civ. Engrs., Vol. XVII, No. 7, September, 1930.

[67] "Stream Flow by the Unit Graph Method," *Engineering News-Record*, Vol. 108, 1932, p. 501; and "Studies of Relations of Rainfall and Run-Off in the United States," *Water Supply Paper 772*, U. S. Geological Survey.

The writer has analyzed the 1936 flood on the Connecticut River, at Sunderland, Mass., and on the Merrimac, at Lowell, Mass., comparing it with other floods. Fig. 22(*a*), shows the flood hydrographs of 1913, 1927, and 1933, on the Connecticut River, at Sunderland (8 000 sq miles), and that of 1936 at Montague City, Mass. (7 940 sq miles). Fig. 22(*b*) shows the same flood hydrographs after deducting the base flow in each case. The similarity of the length of the base of the hydrograph for these different floods is clearly shown.



Date of Flood	Peak Flow Cu Ft per Sec	Base Flow Cu Ft per Sec	Flood Run-off	
			Peak Cu Ft per Sec	Inches
1936	237 000	63 000	174 000	3.77
1927	179 000	8 500	170 500	3.31
1933	137 000	46 000	91 000	2.18
1913	107 000	43 000	64 000	1.38

FIG. 22.—FLOOD HYDROGRAPHS, CONNECTICUT RIVER AT SUNDERLAND, MASS. (1936, MONTAGUE CITY).

There is some variation possible in the value taken for the base flow. It has been assumed as constant throughout the flood period and, in most cases, equal to the flow existing just before the flood rise began. Usually, this is slightly less than the flow remaining at the end of the flood period, as the flood flow tends to diminish after the peak at a slower rate than it increases to the peak. In some cases, where the run-off before the flood was larger than afterward, it has been taken at somewhat less so as to include the entire flood run-off. A small difference in the quantity of base run-off does not greatly affect the characteristic curve. It may be argued that for the 1936 flood this was not a base flow, strictly speaking, but was a part of the first flood that had not yet run off. This is undoubtedly true, although an examination of the hydrographs and of the rates of diminution of snow on the ground during the period between the two storms seems to indicate that even if the storm of March 17 to 19 had not occurred, the flow prior to that storm would probably have continued high. In this case it would seem to be immaterial just what made up this base flow, as it is about the same before and after the total flood period.

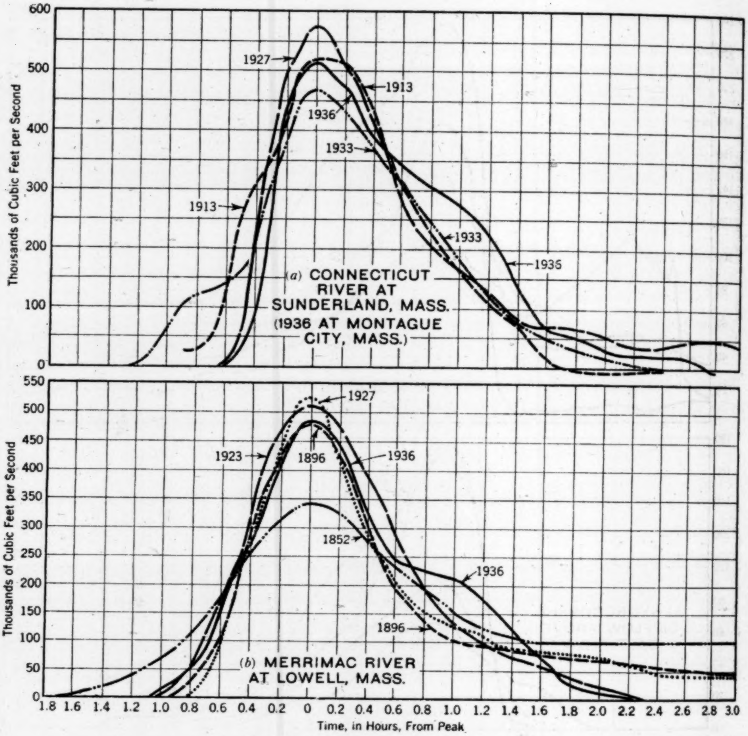


FIG. 23.—CHARACTERISTIC FLOOD CURVES.

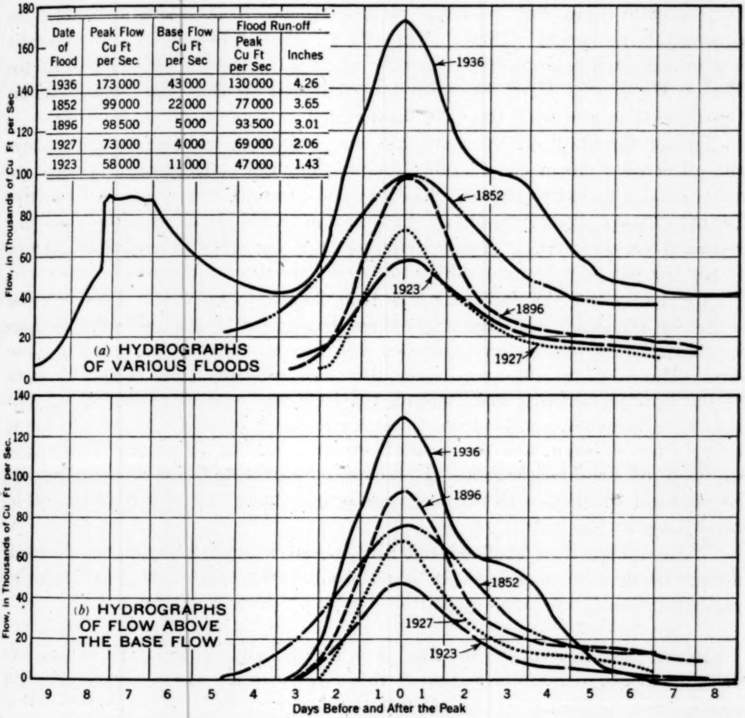
From these "flood run-off" curves the flood characteristic curves shown in Fig. 23(*a*) have been computed. The similarity of these curves for the four floods, with flood run-offs varying from 1.38 in. to 3.77 in., is apparent. That for 1936 is somewhat affected by the additional run-off due to the rainfall of March 21, which shows clearly on the flood hydrograph as a bulge on the curve after the peak. If allowance was made for this condition, the curve would show about the same peak as the curve for 1927.

The 1936 flood on the Connecticut River appears, therefore, as a strictly characteristic flood run-off due to the storm of March 17 to 19, including the consequent melting snow caused by it, superimposed on a very large base flow. The latter was probably largely melting snow although in part it was the remainder of the run-off from the previous storm. The flood run-off, 3.77 in., above the base flow was greater than the previous record run-off of 1927 (3.31 in.), and this was added to a base run-off of 8.0 cu ft per sec per sq mile (equivalent to 0.3 in. of run-off per day). The question of what is the total run-off including the base flow will depend on the period taken. It seems preferable to express the flood run-off in inches for the total, but



Date of Flood	Peak Flow Cu Ft per Sec	Base Flow Cu Ft per Sec	Flood Run-off	
			Peak Cu Ft per Sec	Inches
1936	173 000	43 000	130 000	4.26
1852	99 000	22 000	77 000	3.65
1896	98 500	5 000	93 500	3.01
1927	73 000	4 000	69 000	2.06
1923	58 000	11 000	47 000	1.43

FIG. 24.—FLOOD HYDROGRAPHS OF MERRIMAC RIVER, AT LOWELL, MASS.

the base flow as a rate, continuing as it does before and after the flood period.

Fig. 24(*a*) shows the same hydrographs of various floods at Lowell. These hydrographs are taken from those given by the Committee on Floods of the Boston Society of Civil Engineers,[68] to which has been added the hydrograph of the 1936 flood. Fig. 24(*b*) shows these floods after deducting the base flows. On the Merrimac River the flood run-off above the base flow was greater than any previously recorded flood (1852) by 17%, and 40% greater than any previous recorded flood from a storm within the concentration period (1896). Fig. 23(*b*) shows the flood characteristic curves also taken from the report[69] of the Committee on Floods of the Boston Society of Civil Engineers, re-arranged so that the peaks come at the same time and with the 1936 flood added.

Except for the flood characteristic curve of 1852, which apparently shows the effect of a storm considerably longer than the concentration period, the same similarity exists and the flood of 1936 presents the same characteristic. In this case a flood run-off of 4.26 in., in itself much greater than any recorded previous flood, was superimposed on the high base flow of 10.8 cu ft per sec per sq mile, equivalent to 0.4 in. per day of run-off.

Mr. Uhl notes the fact that the 1936 flood generally was relatively less severe on the small drainage areas than that of 1927. Excluding differences in rainfall this was generally due to two factors: First, the storm of three days (March 17 to 19) was longer than the concentration period of many of the smaller streams; and, second, the base flow was a small part of what may be expected for a flood on a small stream; 8 to 10 cu ft per sec per sq mile is not a large flow for a small stream, but on the larger rivers it is in itself of flood magnitude. The base flow of the Connecticut River, at Sunderland (63 000 cu ft per sec) was larger than 27% of the annual 24-hr flood flows in the last 55 yr.

With a base flow of flood magnitude and a superimposed flood run-off greater than any on record, it is no wonder that the 1936 flood exceeded previous records by large quantities on many New England rivers.

RALPH W. POWELL,[70] M. AM. SOC. C. E. (by letter).—It is scarcely possible to exaggerate the value of this Symposium. Between the time the papers were presented orally (October, 1936) and their appearance in *Proceedings* (March, 1937) another flood occurred on the Lower Ohio River, in most respects more serious than any described in the Symposium. Therefore, some of the statements in the Symposium were already "out of date" when printed, but the importance of the subject was still further emphasized. The fact that it is now a national problem is clear from the wording of the Flood Control Act of 1936.

[68] *Journal*, Boston Soc. of Civ. Engrs., Vol. XVII, No. 7, September, 1930, Fig. 16, p. 384.

[69] *Loc. cit.*, Fig. 18, p. 394.

[70] Assoc. Prof. of Mechanics, Ohio State Univ., Columbus, Ohio; formerly, Hydr. Engr., Muskingum Watershed Conservancy Dist., New Philadelphia, Ohio.

With the exception of those few non-navigable streams that discharge directly into the ocean or into the Great Lakes, the control of floods on any stream in the United States is now "a proper activity of the Federal Government in co-operation with States, their political subdivisions, and localities thereof."

One minor correction might be offered to Mr. Jacobs' valuable paper. Under the heading, "Engineering Aspects," he states that three of the Muskingum reservoirs are automatic retention basins. Probably the three reservoirs meant are the Mohawk, Mohicanville, and Bolivar. These are "dry reservoirs," but the outlets are gate-controlled. Of course, with the gates open, the reservoirs would still give a certain volume of automatic storage just as they did in the January, 1937, flood when the gates were kept open due to legal reasons; but, normally, the gates will be closed as soon as it appears that the safe capacity of the channel down stream would otherwise be exceeded.

The Pleasant Hill Reservoir has an automatic outlet (orifices in an intake tower), but it is not a simple retention basin, as it has 13 500 acre-ft of permanent storage that can be released through two 3.5 by 7-ft sluice-gates. Since these gates are normally under a head of about 45 ft, they could, if it were desired, afford an appreciable controlled discharge in addition to the automatic discharge through the orifices. The original plans called for gates in the orifices also, but this was ruled out by the consulting board as one more complication in an already complicated design.

Of the plotting of discharge per square mile against drainage area (as in Fig. 3, presented by Mr. Uhl, and in Fig. 13, presented by Messrs. Harrington and Johnston) there is no end, and the graphs are always interesting. The latest to come to the writer's attention is by Victor H. Cochrane,[71] M. Am. Soc. C. E. It would seem to the writer, however, that they would be much more valuable if the data were limited to the maximum annual floods over the entire period of record of a large number of streams. Then a line or a smooth curve which had 1% of the points outside it might be thought of as representing a 100-yr probability; one with 5% of the points outside it, a 20-yr probability; etc. It must always be remembered, however, that drainage area is only one of the factors determining probable peak discharge. The arrangement of tributaries, whether fan-shaped and converging on the point considered, as at Pittsburgh, Pa., and Dayton, Ohio, or with various concentration periods, as in the Mississippi River at New Orleans, La., plays an extremely important part. As C. R. Pettis, M. Am. Soc. C. E., has shown,[72] the average width of the drainage area is probably a better criterion than the total area, and a plotting of peak flow against average width might be the best way to represent the data.

In spite of its obviousness, furthermore, attention should be called to the fact that it is only in the design of channel improvements, levees, bridge openings, etc., that the unmodified peak flow is important. If the flow is to be controlled by reservoirs, the essential item is the volume of the entire flood hydrograph. Fortunately this can be estimated much more accurately than the peak flow, since for safety it must be taken as equal to, or nearly equal to, the entire rainfall over the drainage area; and the data on rainfall are much more extensive than those on run-off.

---

[71] *Engineering News-Record,* November 25, 1937, p. 867.

[72] "Floods in the United States," U. S. Geological Survey, *Water Supply Paper No. 771,* p. 36.

In this connection the writer feels that Messrs. Morse and Thomas have erred in their treatment of the effects of forests. The run-off from light and medium rains is greatly affected by the cover, and a good forest should definitely reduce the average annual flood. For the great floods upon which the design of adequate flood control must be based, however, it is doubtful whether the retention would be a large enough part of the entire precipitation to affect greatly the design. For example, the January, 1937, flood at Louisville, Ky., would probably have been almost as great if the same rainfall had fallen 200 yr earlier. Certainly accurate quantitative data on the subject are greatly to be desired.

With the remarks of Messrs. Morse and Thomas on "flood routing" and on the importance of the experiments at the Carnegie Institute of Technology, at Pittsburgh, the writer is in hearty accord. Some have felt that the Burns-Harkness-McCarthy method is a satisfactory solution of the problem, but the writer's experience is that the ratio of storage increment to the corresponding weighted flow increment is not the same for great floods as it is for medium-sized floods, and that it is not the same for winter floods as for summer floods. To be able to compute the effect at all points down stream, of storing or discharging at given rates from each reservoir, is so necessary for flood forecasting as well as for the design of control systems, that the problem is probably the most important one confronting flood control engineers. Fortunately, sufficiently complicated systems are now in existence on such rivers as the Tennessee and Muskingum, to try out, by full-scale experiment with small floods, any theory or method of computation proposed.

Franklin F. Snyder,[73] Jun. Am. Soc. C. E. (by letter).—In the part of their paper discussing the U. S. Weather Bureau relation to the 1936 flood at Pittsburgh, Messrs. Morse and Thomas compare a stage prediction made at 8:00 A.M. on March 17, 1936, for the forenoon of March 18, with the observed stage at 8:00 A.M., March 18, and arrive at an error of 10 ft. From the data now available it appears that the forecast made on 8:00 A.M., March 17, was not more than 3 ft in error. The aforementioned type of comparison and conclusion is often made and illustrates the care that must be taken to make clear the basis for any particular forecast. Studies for the improvement of existing flood forecasting methods, made co-operatively by the Pennsylvania Department of Forests and Waters, the U. S. Weather Bureau, and the U. S. Geological Survey, were begun in 1937, and, in this connection, some interesting aspects of the 1936 flood at Pittsburgh, Pa., have been developed.

Procedures of river forecasting on head-water areas are based on data accumulated only a short time before the forecast is released. Progress is being made in weather forecasting, and particularly in air-mass analysis, which indicates possibilities of forecasting rainfall quantitatively, but, until such developments reach a state of practical application, forecasts, as issued, must be understood to apply to flow from rain already fallen.

---

[73] Hydr. Engr., Dept. of Forests and Waters, Commonwealth of Pennsylvania, Harrisburg, Pa.

The interval between the time of critical rainfall and that in which the resulting flood can be identified in the principal channel system is appreciable in most cases. The unit graph procedure provides an opportunity to demonstrate this point.

In analyzing the March, 1936, flood at Pittsburgh, the Allegheny River was studied at Dam No. 3 (drainage area, 11 530 sq miles) which is 14.5 miles up stream from the junction. On the Monongahela River, Dam No. 2 (drainage area, 7 340 sq miles), 11.2 miles up stream from the junction, was used. The surface run-off hydrographs were computed at these two stations and added to the Pittsburgh base flow to obtain the computed hydrographs of Fig. 25.

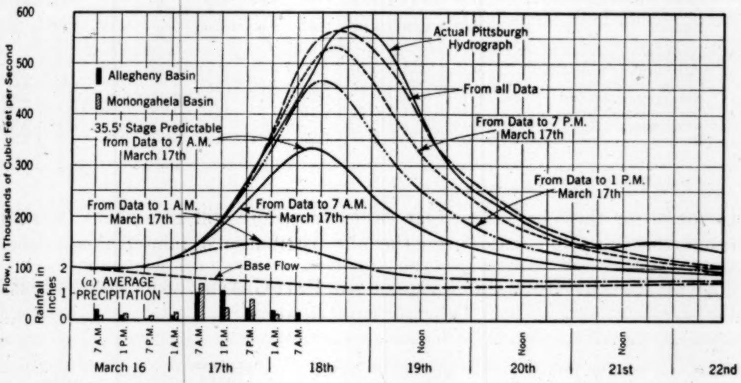

FIG. 25.—FLOOD OF MARCH, 1936, AT PITTSBURGH, PA.

Nineteen selected precipitation stations were used on the Allegheny Basin. They gave an average depth of 3.94 in. of precipitation for the period, March 16–19, 1936, of which the last 0.63 in. was classified as snow and was eliminated from the study for the period after 7:00 A.M. on March 18. The unit graphs used were designed for 6-hr rainfall data, the basin precipitation being divided into 6-hr intervals according to the precipitation recorded automatically at the Piney Plant of the Pennsylvania Electric Company, on the Clarion River (see Table 14).

Snowfall equivalent to 0.50 in. of water was added and assumed to melt in proportion to the precipitation for lack of a better method. This gave 3.81 in. of water depth to be accounted for and, with an initial loss of 0.25 in. deducted from the rainfall of the first period, left 3.56 in. The estimated volume of surface run-off was 1.95 in., giving a surface run-off factor of 54.8 per cent. This factor is not a real one since only enough run-off occurred from the precipitation above Franklin, Pa. (mostly melted snow) to maintain a recession flow of 42 000 cu ft per sec from the previous rise to give a peak of 50 000 at midnight, March 17–18.

Another way to express the run-off factor, more in accord with the actual conditions (that is, the area above Franklin eliminated), is based upon a depth of precipitation plus water equivalent of snow of 5.00 in., with a surface run-off volume of 3.75 in., giving a run-off coefficient of 75% for the lower area. It will be found for this illustration that either procedure will give about the same result, the controlling factor being the 6-hr distribution of rainfall as established

by the Piney record. However, since the depths used are those for the entire area, the unit graph applied is that designed for conditions prevailing when the greater run-off comes from the lower basin.

Twenty-five precipitation stations were used on the Monongahela Basin and, for the period, March 16–19, 1936, gave an average of 3.54 in., of which the last 0.47 in. was classified as snow assumed to have fallen after midnight of March 17–18. The water content of melting snow was assumed at 0.50 in. With an initial loss of 0.16 in., the remaining 3.41 in., together with a surface run-off factor of 80.5%, provided the desired volume of 2.75 in. of surface run-off. The precipitation period was divided into 6-hr intervals according to the average of the recorded rainfall records of the U. S. Weather Bureau stations at Pittsburgh, and at Elkins, W. Va., as shown in Table 14. The unit graph applied was that designed for use with a fairly uniform distribution of run-off.

Six-hour ordinates of the unit graphs and their corresponding distribution graphs are given in Table 15. The first value is to be plotted at the middle of the first 6-hr run-off period and the successive values at 6-hr intervals.

No time correction was applied to the computed surface run-off data for the time lag between Dam No. 2 and Dam No. 3 and Pittsburgh. The actual Pittsburgh hydrograph is also shown, and is based on a Pittsburgh rating obtained by gage relations from the U. S. Geological Survey Station at Sewickley, Pa.

The foregoing example is presented to illustrate the situation that must be taken care of when forecasts are to be issued at regular intervals. Certainly this must be done on head-water areas where, if the forecast were delayed until the cessation of rainfall, the opportunity for preparation would be largely lost. The illustration is not intended as a demonstration of the unit graph procedure nor as a justification or criticism of any actual forecasts. A considerable part of the study was prepared by R. J. MacConnell, of the Pennsylvania Department of Forests and Waters.

W. F. UHL,[74] M. AM. SOC. C. E. (by letter).—To the many engineers who have contributed discussion to his paper, the writer is indebted. Mr. Williams' discussion of the basis for computing flood damages, which he illustrates by reference to the Winooski River, is helpful. The writer agrees with Mr. Williams that the humanitarian aspect of flood control should not be stressed to the point of causing a community to assume a burden which threatens its financial ability.

By his account of the flood at Lowell, Mass., Mr. Safford has described the effect of the greatest flood on record on one of the old water-power cities of New England. The damage that occurred, and the problem of flood control as it affects Lowell is probably typical of the situation in New England cities situated on the larger rivers. In his study of flood frequency on the Lower Connecticut River, Professor Barrows has made use of one of the longest records of flood stages in the United States—that of the Connecticut River, at Hartford, Conn. The fact that he has developed two extension curves from these data illustrates the difficulty of establishing an accurate basis for computing the frequency of floods of certain magnitudes.

---

[74] Hydr. Engr., Chas. T. Main, Inc., Boston, Mass.

Mr. Bush questions whether it is possible to operate reservoirs, built for the dual purpose of power storage and flood control, in such a way that the flood-control aspect will be fully safeguarded. In such a dual-purpose reservoir, unquestionably some of the effectiveness of a given reservoir for power-storage purposes will have to be sacrificed to the requirements of flood control. In New England, at the present time, there are several instances of power-storage reservoirs subject to regulations dictated by the recreational uses of the reservoir, which impair their effectiveness as power-storage reservoirs; for instance, the operation of Lake Winnepesaukee is subject to State regulations which limit the draft during the summer months. It is a fact that the recreational uses of these reservoirs have been safeguarded by these regulations. Therefore, it seems reasonable to suppose that, in the case of reservoirs built for the dual use of power storage and flood control, it would be possible to control the operation by regulations which would safeguard the requirements of flood control.

The writer agrees with Mr. Turner that the isohyetal lines of very high rainfall in the second storm, as shown in Fig. 5, probably did not extend as far west as is shown. An exact determination of the area covered by the 10-in. and the 8-in. rainfall is an interesting subject of speculation, but there are not sufficient data available to arrive at a definite answer to the problem. Mr. Turner's study of the major peak of the 1936 flood on the Connecticut and Merrimac Rivers [66] is a valuable contribution to the subject of New England floods.

The writer wishes to point out that his paper was written while the work of collecting and analyzing the data on the March, 1936, floods was still in process. As a result, many of the figures given in the paper, particularly those of 1936 peak discharges, are subject to change. In general, the changes are so small that it seems unnecessary to revise the original data. The revised values are available in some of the more recent papers on this subject.[75]

ARTHUR W. HARRINGTON,[76] M. AM. SOC. C. E., AND HOLLISTER JOHNSON,[77] Assoc. M. AM. SOC. C. E. (by letter).—Since the presentation of the writers' paper, the U. S. Geological Survey has completed a number of papers and reports pertinent to the subject of this paper. One series, of three parts, concerns "The Floods of March, 1936." [78] In these volumes are presented records of stage and discharge at river-measurement stations, contents of storage reservoirs, peak discharges and stages with comparative data for other floods, crest stages, precipitation, the depth and water content of snow on the ground, the results of studies of rainfall and run-off, and many other kinds of flood information.

The writers are grateful to Mr. Hendricks for his discussion of the floods of 1935 and 1936, with special reference to their occurrence and relation to previous floods in the basins of the Mohawk and Oswego Rivers.

---

[75] See, especially, "The Floods of March, 1936, Part I, New England Rivers," *Water Supply Paper 798*, U. S. Geological Survey.

[76] Dist. Engr., U. S. Geological Survey, Albany, N. Y.

[77] Hydr. Engr., U. S. Geological Survey, Albany, N. Y.

[78] "Part 1, New England Rivers," *Water Supply Paper No. 798;* "Part 2, Hudson River to Susquehanna River Region," *Water Supply Paper No. 799;* and "Part 3, Potomac, James, and Upper Ohio Rivers," *Water Supply Paper No. 800.*

Professor Powell has a very interesting idea of plotting drainage area against the discharge per square mile for the maximum annual floods over the entire period of record of a large number of streams and representing the 100-yr probability by a line or smooth curve which would have 1% of the points outside it; the 20-yr probability by the line with 5% of the points outside it, etc. However, some difficulties might be encountered in establishing a criterion by which to judge the distribution of the points along the line and thus determine the slope of the line. If some reasonable criterion was not used it would be easily possible to produce an absurd interpretation that would show increases in unit discharges with increases in drainage areas which, of course, is generally not true. It is the writers' belief that, if, before plotting, the discharges per square mile were corrected for channel storage (thus representing the unit rate of run-off into the channel rather than the unit rate of run-off in the channel past the measuring point) the resulting chart would represent more nearly unit rates of run-off which might be expected to occur in streams in the same locality but with perhaps much less channel storage.

It appears that there is unanimity of opinion among engineers and others as to the need for the development of a national flood-protection policy and that one of the essentials for the evolution of such a policy is the availability of the hydrologic data which are so basic and fundamental in any study and investigation of the control of water. Including the aforementioned series,[78] the U. S. Geological Survey has prepared reports on ten notable and outstanding floods which have occurred since 1934. These reports[79] were planned as an effort to present such basic hydrologic data (especially that of precipitation and stream flow) as were available at the time of publication.

MERRILL BERNARD,[80] M. AM. SOC. C. E. (by letter).—It is gratifying to report that field headquarters for five of the hydrologic regions planned by Mr. Hayes were established early in 1938. Other gains in expanding and strengthening the service have been made, one of the most important being a co-operative program between the Commonwealth of Pennsylvania, through its Water and Power Resources Board, the U. S. Weather Bureau, and the U. S. Geological Survey. This co-operative project is providing the means to establish a modern forecasting service on the Allegheny, Monongahela, Susquehanna, and Delaware Rivers.

Modern methods of estimating stream flow from rainfall extend the analysis into the relatively small water-sheds comprising the river basin. The procedure involves short concentration periods, and rainfall rates of short duration and high intensity. Obviously, rainfall rates recorded as averages for 24 hr cannot be used in studies on water-sheds of 50 to 500 sq miles having concentration periods of 2 to 6 hr. Therefore, the first step in the aforementioned co-operative program has been to establish, over the river basins comprising the project, a net of approximately 130 recording rain-gages having an average density of 400 sq miles per gage.

[80] Mr. Hayes died on November 16, 1936. This closing discussion on his paper was prepared by Merrill Bernard, M. Am. Soc. C. E., who succeeded Mr. Hayes as Chf. of the River and Flood Div., U. S. Weather Bureau, Washington, D. C., on March 5, 1937.

These recording rainfall stations have been classified as: (1) Those that are located primarily to provide data for the hydrologic studies from which forecasting methods are to be developed; and (2) those that are to serve ultimately as reporting rainfall stations under the established forecasting procedure. Stations in the first group have been located so as to give proper weight to geographic position in the net, area representation, elevation, and aspect, without depending upon local attendance. Those in the second group have been located at strategic points where qualified 24-hr attendance is available and dependable communication assured.

Practically all the rainfall stations are accessible over paved highways and have been located on three circuits over which experienced hydrologic engineers travel on schedule. These engineers are charged with the duties of servicing the gages, assembling the charts, and tabulating the data for immediate use. During the winter months they will conduct snow surveys and keep themselves informed of day-by-day changes in run-off conditions.

In general, the procedure at the forecasting centers will be as follows:

(*a*) A day-by-day estimate of run-off potentialities based upon the discharge from index water-sheds, the estimate to include the possible contribution to run-off from an existing snow mantle;

(*b*) A day-by-day check on storm approach, utilizing the general weather service of the Weather Bureau, and particularly the weather maps prepared at frequent intervals at the aerological stations;

(*c*) With the beginning of a critical storm period, the reception of hourly (or other-period) rainfall by telephone and telegraph, or by amateur and automatic radio broadcasting;

(*d*) The preparation of an isohyetal map for each period showing the progressive accumulation of rainfall depth over the basin;

(*e*) Under a well organized and largely mechanical technique, the conversion of rainfall into stream-flow hydrographs;

(*f*) The conversion of rates of stream flow to river stage at points down stream for which a forecasting service is rendered; and,

(*g*) As quickly as rainfall has ceased, the prompt announcement, through established channels, of flood-peak stage and the hour of the arrival of the flood's crest.

Mr. Snyder has given an interesting picture of the March, 1936, flood at Pittsburgh, Pa., based upon a critical review of the meager data available and an application of the unit graph method of estimating stream flow.

The unit hydrograph is found to be an excellent tool for forecasting, as his discussion indicates. As data are made available through the newly established network of recording rainfall gages, refinements in the method and time-saving devices in procedure can be expected to develop. His study constitutes an important step in the establishment of a modern forecasting plan for Pittsburgh.

In closing the incident of the forecasts of the March, 1936, flood at Pittsburgh, it seems appropriate to comment upon the courage which it must have taken to issue an unprecedented forecast based upon the most meager data, and dependent upon a method in which judgment gained from personal experience was the predominating factor.

Mr. Scobey has called attention to the important place snowfall has in the genesis of floods, particularly on Western streams where flow is comprised largely of run-off from snow melting.

In the mountainous States of the West forecasts of the seasonal yield of the snow mantle, expressed as a percentage of the normal for the basin, are determined from surveys made toward the end of the snowfall season. The obvious need for a quantitative forecast—that is, a forecast in terms of the hydrograph of flow—has stimulated an interest in the Weather Bureau's investigations of snowfall gages, the most promising type being one in which the snow is melted as it falls into the gage with a salt brine, the catch stabilized against wind action with a flexible shield, and the contents of the gage protected against evaporation by an oil film.

The snow course lends a real significance to the record by virtue of its length. Likewise, the snowfall stations of the Bureau will utilize sampling areas, carefully selected as typical, upon which are placed batteries of storage snow gages, the average record of the group being considered applicable to the part of the basin represented by the snowfall station. The average water depth for the group (usually five gages) is determined by the simple expedient of weighing, under which procedure the increment increase in weight between weighings becomes the snowfall for the period, expressed in inches. Batteries of such gages have been established at twenty stations having elevations greater than 7 000 ft. Gratifying experience to date (1938) indicates that they have the following advantages over other methods of determining the water equivalent of snowfall under Western conditions: (1) They measure snow as it falls and before it is subjected to prolonged wind action; (2) they secure the record against loss through poor attendance or failure to reach the station before a critical period of melting; (3) they function at all elevations, including the transition zone from snowfall to rainfall; (4) they are inexpensive to install and require a minimum of attendance; (5) they are not dependent upon tree shelter for stability of record; and (6) precipitation in the form of snow can be recorded as daily precipitation through the simple procedure of daily weighing.

One hesitates to take up the gauntlet in Mr. Meursinge's good-humored jibe at American engineers for their temerity in attempting to determine possible maximum run-off of the Ohio and Mississippi Rivers. Such optimism has evidenced itself in the newly established hydro-meteorological studies of the Weather Bureau set up co-operatively with the U. S. Corps of Engineers. The study undertakes to provide the meteorological and hydrological background of the great storms of record and the justification for their transposition to basins other than those embraced actually by the critical storm area.

Mr. Houk has sensed the weakness in any head-water forecasting service to meet the situation developing around the highly intense cloudburst type of storm which can develop locally and may not be associated with a period of general rainfall.

Two circumstances may mitigate toward a practical solution of such forecasting problems:

(*a*) *Plans for an Expanded Network of Recording and Reporting Rainfall Stations.*—The density of the co-operative network in Pennsylvania is approximately 1 gage to 400 sq miles. Recent estimates for networks on problem areas in the Mississippi Basin provide a recording rain-gage to each 100 sq miles on the average.

(*b*) *The Rapid Expansion of the Network of Aerological Stations of the U. S. Weather Bureau.*—These stations, located at the active airports of the United States, serve aviation and issue a weather map at 6-hr intervals from transmitted signals which include the results of upper-air soundings.

It is planned to make full use of these aerological stations in the river and flood forecasting service of the Weather Bureau.

Head-water flood-warning services are being inaugurated (1938) by the Bureau in co-operation with the Cities of Cumberland, Md.; Johnstown, Pa.; and Elkins, W. Va. In these instances no immediate attempt is being made to forecast flood stages, but a carefully organized warning service is intended which will utilize municipal departments, railroad and utility company communication facilities, and the services of municipal officials and employees whose interests insure an alert and efficient attendance.

The snow work of the Weather Bureau has been commented upon briefly in the discussion by Mr. Scobey. Mr. Field has emphasized the need for quantitative forecasts of run-off from melting snow. Under conditions in the Central and Eastern States, where periodic melting may remove the snow mantle several times during the winter months, it is necessary to know, day by day, the potential run-off in an existing snow cover, and an adequate forecasting system must provide for the measurement of the factors that may combine to release such run-off. Under Western conditions, where there is no appreciable loss through the winter, the problem of quantitative forecasting will be largely that of measuring factors, such as temperature, concurrent rainfall, and ground surface conditions, as well as snowfall measurements at a sufficient number of points in a basin to give dimensional significance to the average depth of snow and water equivalent. The gathering of such data involves remote observational points at high elevations where attendance is difficult or impossible and emphasizes the obvious need for automatic recording seasonal snow gages.

The greatest obstacles to be overcome in the re-organization and expansion of the Bureau's river and flood forecasting service is a general lack of understanding of its functions, inadequate financing, and the difficulties of adjusting cost to benefit. The responsibility as well as the expense of a flood-forecasting service should shift in varying degrees from the Federal Government only, to a co-operation with other interests as head-waters are approached and as problems become more and more localized. This transition in economic responsibility is accompanied by marked changes in method. Thus, in flood control, levee systems only give way to combinations with reservoirs and organized land-use practices over large areas. Likewise, methods of river forecasting which have met successfully the conditions of lower river flow must be elaborated to take into account the many factors influencing smaller stream flow, the principal one of which is rainfall.

On the larger river systems the objective for the service is an integrated forecast from head-waters to outlet. This is best understood by conceiving the principal channel of the river as divided into reaches of known channel storage. It can be stated, then, that the discharge from the lower end of any reach throughout a fixed interval of time is equal to the discharge into the upper end from the reach above, plus the inflow of tributary streams entering throughout the length of the reach, plus or minus any change in storage that has occurred within the time interval. The travel of the flood wave through the reach must be taken into account. This takes the form of a progressive distortion in the shape of the storage prism throughout length and through time, and, under fixed conditions of inflow and outflow, may prove to be fairly constant. The most effective method of forecasting on a large river such as the Mississippi must begin at the head-waters, and on all important tributaries simultaneously, and must provide the means of transmitting hydrologic data and estimates of flow progressively down stream to the important forecasting centers along the main river stem.

The average annual flood loss to the nation as reported to the Weather Bureau is about $100 000 000. It is believed that this sum can be reduced materially by increasing the period of the forecast so that greater opportunity is provided for the removal of perishable goods and property and for the evacuation and protection of areas doomed to inundation by the oncoming flood. The cost of providing the additional preparation opportunity will prove negligible when compared with the resulting reduction in loss of life, human misery, and property damage.

The answer to the problem of minimizing national flood hazard does not lie in the permanent evacuation of the flood plains of the great rivers. Man has profited greatly by utilizing these fertile lands during such time as the rivers have not needed them to pass their flood waters to the sea. He should, and does, however, pay a rental for his occupancy, either in the continuing cost of protection works or in the periodic repair of flood damage. This cost could be reduced and, in many cases, nearly eliminated through a co-ordinated program of flood protection, flood warning, and flood insurance—all within the realm of practicability, as demonstrated in the several European countries pioneering in this field.

As the modern automatic fire alarm system is to be credited largely with the immunity now enjoyed from the catastrophic conflagrations that occurred all too frequently through the past half century, so should a modernized flood-forecasting service pave the way to a more secure and intelligent use of the river valleys of the United States.

THE PASSAGE OF TURBID WATER THROUGH LAKE MEAD

BY NATHAN C. GROVER,[1] M. AM. SOC. C. E., AND
CHARLES S. HOWARD,[2] ESQ.

WITH DISCUSSION BY MESSRS. O. A. FARIS, PAUL A. JONES, CARL S. SCOFIELD, IVAN E. HOUK, WILLIAM P. CREAGER, HAROLD K. PALMER, MORROUGH P. O'BRIEN, JOHN C. PAGE, JOHN H. BLISS, B. H. MONISH, D. M. FORESTER, A. D. LEWIS, G. C. DOBSON, WILLIAM W. RUBEY, J. C. STEVENS, C. S. JARVIS, R. E. REDDEN, RAYMOND A. HILL, AND NATHAN C. GROVER AND CHARLES S. HOWARD.

SYNOPSIS

Turbid water carrying a considerable load of fine silt was discharged from Lake Mead, above Boulder Dam, in Arizona and Nevada, at three different periods during 1935 when the reservoir was 70 to 90 miles long and contained from 4 000 000 to 5 000 000 acre-ft of water. Apparently, it flowed through the reservoir essentially unmixed. Chemical analyses of the water entering into, and discharged from, the reservoir corroborate the conclusions drawn from the observations of silt as to the occasional discharge of essentially unmixed water. The phenomenon is ascribed to the greater specific gravity of the incoming water relative to the generally clear water at the surface of the lake, due probably, in part, to its silt load. A practical significance is suggested with respect to the possibility of increasing the passage of fine silt through a reservoir, thereby prolonging its effective life. References are made to other known occurrences of similar phenomena.

INTRODUCTION

The apparent resistance of water to mixing, under certain conditions, is a matter of common knowledge based on many observations. A river having water of one color receives a tributary having water of another color,

---

NOTE.—By decision of February 1, 1936, by the Board on Geographical Names, the reservoir formed by Boulder Dam on Colorado River in Arizona and Nevada, was named Lake Mead, in honor of the late Elwood Mead, M. Am. Soc. C. E. This paper is published by permission of the Director, U. S. Geological Survey. The paper was published in April, 1937, *Proceedings*.

[1] Chf. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

[2] Chemist, U. S. Geological Survey, Washington, D. C.

and the two waters flow for miles side by side in the same channel without very much mixing. The Gulf Stream flows for hundreds of miles through the Atlantic Ocean and retains such definiteness of boundaries (identified by color, temperature, and organic matter), that a ship's bow may be situated within, and its stern outside, the stream. The late John R. Freeman,[3] Past-President and Hon. M. Am. Soc. C. E., calls attention to rivers that discharge turbid water into the clear water of lakes. The phenomenon may be seen as the current cascades to considerable depths practically unmixed with the clear lake waters through which it is falling. The flowing of one water through, or by the side of, another water without rapid mixing might be illustrated by many examples.

There is one type of the failure of water to mix which has not been so commonly observed and has not been adequately recorded in engineering literature, but which may be of great interest and perhaps practical value to engineers. This type relates to the flow of turbid water through a reservoir of great length and its discharge at the dam with its conspicuous characteristics unchanged. Obviously, as the discharge of turbid water from a reservoir does not occur at all times when such water is flowing into it, there must be certain conditions of the inflowing water related to its specific gravity, viscosity, temperature, size, and degree of dispersion of the silt particles (or other physical qualities and combinations of them), that are prerequisite to such discharge. Although such discharges have been mentioned occasionally in engineering literature, the conditions under which they occur have not, as far as the writers are informed, been thoroughly described or studied. Mr. H. F. Robinson[4] quotes a report made in 1914 by Rollin Ritter, Assoc. M. Am. Soc. C. E., that "the silt-laden waters, being heavier than the clear, oftimes appeared at the tunnel outlet when the reservoir surface was clear and a small or moderate flood was entering the reservoir." Such a flow of turbid water through a long reservoir has been observed at Lake Murray, about 30 miles long, on the Saluda River, in South Carolina. L. M. Lawson,[5] M. Am. Soc. C. E., has mentioned the discharge of silt through the gates of Elephant Butte Dam on the Rio Grande, in New Mexico. Mr. L. R. Fiock[6] states that flows of turbid water from the Elephant Butte Reservoir, the head of which has been 30 to 40 miles above the dam, have occurred in 7 yr out of 20 yr of its operation. The movement of turbid water through the lake formed by Boulder Dam has also been mentioned.[7]

Measurements by Mr. H. M. Eakin,[8] of the sediments deposited in many reservoirs, appear to indicate similar flows of unmixed waters through reservoirs of various lengths and characteristics. He reports that his measurements disclose two types of deposition of sediment in a reservoir—in delta areas adjacent to points of stream inflow and in the deeper parts of the reservoir. The deposition of sediment in the deep parts near the dam are explained by him on the hypothesis that turbid water passed through the reservoir from the point of entrance.

Colorado River and Lake Mead

The Colorado River normally carries large quantities of silt. Under natural conditions this silt moves down the river channel, in part continuously and in part by stages of alternate deposition and erosion. Except as modified by gradual degradation or aggradation of the channel, as much silt would normally pass one point on the river over a considerable period of time as would pass another point, due allowance being made for accretions from tributaries; but within short periods there would not be such equality of silt movement.

Lake Mead was created by the construction of Boulder Dam, about 600 ft high, above the stream bed (731 ft from the lowest point in the foundation to the highest point of the dam), in the Black Canyon of the Colorado River. The lake thus formed has an initial capacity, at spillway level, of 30 500 000 acre-ft, which is about the total run-off of the river in two average years. When the reservoir is filled, the lake will have a length of about 115 miles and a surface area of about 145 000 acres. It is irregular not only in outline but in cross-section. Within it are several box, or near-box, canyons through which the Colorado River flows, ranging from 2 to 10 miles in length, separated by more open valleys into which the lake widens. The lake, therefore, may be considered as composed of several great pools, notably at or near Las Vegas Wash, the Virgin River, Hualpai Wash, and Grand Wash, separated by the relatively narrow necks formed by the canyons. The making of this lake has changed the natural processes of the river within the 115 miles of the lake and, of course, throughout the course of the river below the lake. The annual floods in the river below the lake, with their eroding and transporting action, have been eliminated. In this part of the river the range in stage and discharge is now relatively small. The conditions in the basin above the lake are unchanged, of course, and most of the silt that enters the lake is now (1937) deposited and remains there.

After the filling of the lake had progressed for a short time, the effluent became essentially clear, and, in general, it has continued so since. However, turbid water was discharged from Lake Mead three times during the eleven months from February 1, 1935, when storage began, to December 31, 1935, although the quantity flowing through the openings in the dam throughout the period has been controlled at less than 10 000 cu ft per sec. During these months the water was flowing through the tunnels at the base of the dam, and, when the turbid discharges occurred, the lake was from 70 to 90 miles long and contained from 4 000 000 to 5 000 000 acre-ft of water; there was no significant change in the quantity of outflow. The turbid discharges represent the conveyance through, and the discharge from, the lake of as much as 6 000 000 tons of silt. At these times there has been not only the ocular evidence of unmixed or partly mixed water flowing through the lake, as disclosed by its turbidity, but this evidence has been substantiated by measurements of the size of the particles of suspended matter and by the determination of the dissolved matter, as indicated by the sulfates, contained in the water entering into, and discharged from, the lake.

Measurements and Observations

The loads of suspended matter carried by the Colorado River are computed for the Grand Canyon Gaging Station, about 265 miles above Boulder Dam, and for the Willow Beach and Topock Gaging Stations, about 10 and 115 miles, respectively, below the dam. The positions of these stations with respect to each other and to the lake are shown by Fig. 1. The percentages by weight of suspended matter are given in Table 1 for the Grand Canyon, Willow Beach, and Topock Gaging Stations during the period, March 1 to October 31, 1935. The loads, in tons per day, are shown in Fig. 2 (*c*) for the Grand Canyon and Willow Beach stations.

FIG. 1.—MAP OF COLORADO RIVER DRAINAGE BASIN.

Comparisons of the loads carried past the Grand Canyon and Willow Beach Stations, give an approximate measure of the quantity of material deposited in the lake. Comparisons of the loads carried past the Willow Beach and Topock Stations give a measure of the scouring of the river channel that occurs between those two stations. The results for the Topock Station are not shown in Fig. 2, because with the scales used the curves for Topock could not be distinguished from those for Willow Beach. One of the writers[9] has presented data on the quantities of material carried past the Grand

Canyon, Willow Beach, and Topock Gaging Stations from February to June, 1935.

The sizes of the particles of suspended matter have been determined from samples collected regularly at all stations. The samples have been treated with sodium oxalate for complete dispersion of the material before the determinations of sizes are made. As it is carried by the river, the material is evidently in a state of partial coagulation, which may be a function of: The kind of material carried; the chemical composition of the water in the river at the time the sample is collected; and, perhaps, other factors associated with the source of the material. Because of the impossibility of duplicating the field conditions, it has seemed desirable to disperse all samples, completely, before the determinations are made, in order to obtain reasonably comparable results. However, the dispersion, desirable though it may be for uniformity, may obscure or destroy certain natural conditions that have significance with respect to the passage of unmixed or imperfectly mixed water through Lake Mead.

Laboratory tests using Colorado River water for the settling medium show that a large percentage of the undispersed material has a much faster settling rate than the same material in a state of complete dispersion. It now appears, therefore, that it would be desirable to know the sizes of the

particles as they are actually carried in suspension, inasmuch as it is evidently such sizes that may be most significant with respect to the passage of turbid water through a reservoir. It is probable that determinations should be made of the sizes of the material both as received from the river and after complete dispersion.

The larger sizes of particles have been measured and separated by sieves. However, if a considerable proportion of such matter passes a 200-mesh sieve (diameter of particles 74 microns), further determinations of size are made by observing times of settling in tall cylinders and computing sizes by Stokes' law. The settling method, of course, is not exact, because the separations represent quantities of particles that settle at given rates rather than quantities of particles that have given diameters, and each size group obtained contains particles that are smaller than the size for which the separation was made and that have been carried down with the larger sizes. According to Stokes' law the settling rates are, approximately, 26 ft, 4 ft, and 0.3 ft per hr for 50-micron, 20-micron and 5-micron sizes, respectively.

Fig. 2(*c*) shows the daily load of suspended matter at the Grand Canyon and Willow Beach Gaging Stations during the year ending December 31, 1935. During January, 1935, before the flow of the river was regulated by the dam, the load of suspended matter at the Willow Beach Station was

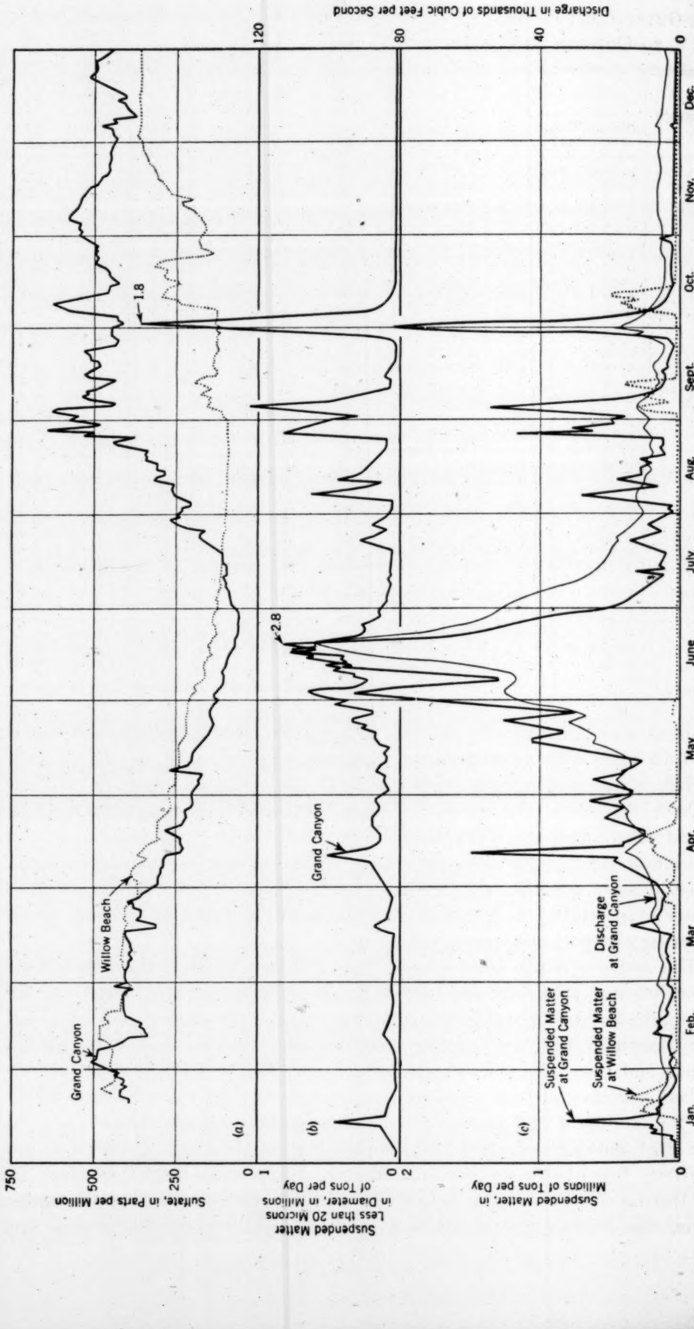

Fig. 2.—Sulfate Suspended Matter, and Discharge at Gaging Stations on Colorado River Near Grand Canyon and Willow Beach, Arizona.

practically the same as that at the Grand Canyon Station and averaged about 100 000 tons per day. After regulation was begun the load of suspended matter at the Willow Beach Station was fairly constant during the first part of February and nearly all of March, averaging about 10 000 tons per day. The nearly horizontal line in Fig. 2(*c*) shows the load of silt at the Willow Beach Station and is a measure of the load picked up between Boulder Dam and Willow Beach by the clear water discharged from Lake Mead. The source of this load has been recently discussed by C. P. Vetter,[10] M. Am. Soc. C. E. The peaks rising above this horizontal line are measures of the load of silt that is being discharged from the reservoir.

There was a slight increase in the suspended load at Willow Beach for a few days, during the latter part of February. However, as shown in Fig. 2, the first outstanding discharge of turbid water from Lake Mead occurred in March and April. In the latter part of March the water discharged at the dam became slightly turbid and continued so for six or seven days. Then, after a week of relatively clear water, the river again became turbid to a greater degree than previously and continued to be turbid for ten days or more. The river became clear in the latter part of April and remained clear until September. The large increase in the load of suspended matter at Willow Beach, in March and April, followed an increase in suspended matter at the Grand Canyon Station. Each subsequent increase at Willow Beach can also be related definitely to a rise at the Grand Canyon Station. Each such increase at Willow Beach appeared about eight days after the rise at Grand Canyon. The records show similarly that each increase at the Willow Beach Station was followed about one day later by an increase at the Topock Station.

During May, June, July, and August, 1935, the river above the lake was carrying considerable suspended matter, which apparently settled completely in the lake, as the river below it was relatively clear during most of that period. The slight turbidity at the Willow Beach Station in that period appeared to be caused by local scouring of the channel and to be accompanied by small eddies or "boils"; and when observed from a cable car 50 to 60 ft above the surface, the river seemed to have spots of relatively clear water interspersed with spots where "boils" were rising from the bed; but the turbidity was too great for actual observation of the bottom. Some of the "boils" did not appear to reach the surface; others came to the surface and created turbulence over rather large areas. It seems likely that this action is normal for the river and that the load of suspended matter normally carried in the lower river at low stages consists generally of material scoured from the river channel.

On September 3, 1935, the river suddenly became turbid at the Willow Beach Station, with practically no change in stage, and continued in this condition until the morning of September 14, when it was again practically clear. During this 12-day period more than 2 000 000 tons of suspended matter was carried past Willow Beach. On September 5, 1935, the river at the Topock Station showed an increase in suspended matter, and for the next twelve days the load at the Topock Station was comparable to the load at Willow Beach, but there was a marked decrease on September 16. The appearance of turbid water at Willow Beach and Topock apparently was related to the large increase in suspended matter in the river water at the Grand Canyon Station, which began August 26 and continued for fourteen days.

---

[10] "Why Desilting Works for the All-American Canal"? by C. P. Vetter, *Engineering News-Record*, Vol. 118, p. 321, (March 4, 1937).

The river at the Willow Beach Station again became turbid on October 6, 1935, and remained in that condition for eight days. On October 14, it had returned to a condition of slight turbidity. During this 8-day period more than 2 500 000 tons of suspended matter was carried past Willow Beach. On October 8, a large increase in suspended matter was observed at the Topock Station, followed by a decrease on October 14 and a return on October 15 to about the conditions of the first seven days of the month. These changes in the quantity of suspended matter below the reservoir apparently resulted from an increase in discharge and suspended matter observed at the Grand Canyon Station for a few days beginning September 27.

SIZES OF PARTICLES

Particular attention is called to the curve in Fig. 2 showing variations in sizes of particles, because it seems likely that the greater specific gravity due to the turbidity of the water, especially when the particles are very fine, may be an important factor in the movement of turbid water through the reservoir.

Fig. 2(*b*) shows the quantity of material with effective diameters of less than 20 microns that is carried daily past the Grand Canyon Station. Whenever there was an increase in the load of suspended matter at the Willow Beach Station there had been a prior increase in the quantity of material less than 20 microns in diameter at Grand Canyon. In each of the periods of turbid discharge, the suspended matter at Willow Beach consisted chiefly of small particles with slow rates of settling, more than 90% of the material being less than 20 microns in diameter.

There will naturally be speculation as to the reason why the high water of May and June, with its heavy silt load at Grand Canyon, did not produce a turbid discharge from Lake Mead. A possible explanation may lie in the fact that, at that time, a high percentage of the silt after dispersion (and probably the percentage was still higher before dispersion) was larger than 20 microns and that this large portion of the silt, with its fast settling rate, carried down with it practically all the finer silt. Determinations of size show that the material carried at Grand Canyon during this period was in a state of partial coagulation and that the sizes of the particles carried were larger than the analyses of the dispersed samples indicate.

During those parts of the period from February to August, when the loads at Willow Beach were small, the suspended material carried past this station consisted chiefly of particles, having diameters greater than 50 microns, picked up in the river channel between the dam and the station. During the same period a slightly larger load was carried past the Topock Station, but the sizes of the particles at the Topock Station were similar to those at the Willow Beach Station. Similar scouring of the river channel at certain periods has been indicated by the results obtained for several years before Boulder Dam was completed. During certain periods of the year (usually in the late fall and winter) before storage in Lake Mead was started, the load at the Topock Station was considerably greater than that at the Grand Canyon Station, and the differences could not be attributed to inflow from tributaries between the stations. It has seemed likely that at these times the river (which probably was not carrying a capacity load at the Grand Canyon Station) had eroded, from the bed and banks, material that had been previously deposited. It is significant that during a period of ten years the samples collected at Grand Canyon have often had less than 0.05% of suspended matter, whereas the samples collected at Topock have rarely had less than 0.10% of suspended matter. At such times of low percentage of suspended matter at the Topock Station, the load has consisted chiefly of particles more than 50 microns in diameter which would drop out of suspension rather easily.

Increases in discharge and suspended matter at the Grand Canyon Station, particularly in the late summer, are frequently caused by rains of high intensity in regions of little vegetation, resulting in rapid run-off of water, high in both dissolved and suspended matter. Herman Stabler,[11] M. Am. Soc. C. E., has presented data indicating that 60% of the suspended matter carried past the Grand Canyon Station came from 36% of the drainage basin lying above that point. The increase in discharge at Grand Canyon on August 26, 1935, was caused largely by an increase in the flow of the Little Colorado River, which drains a large arid region and enters the Colorado 26 miles above the Grand Canyon Station. The material carried by the Little Colorado during certain other summer floods has consisted chiefly of fine particles, and it appears likely that the Little Colorado brought into the Colorado a large part of the material carried past the Grand Canyon Gaging Station on August 26 and a few days subsequent. There is evidence that the Little Colorado and perhaps the San Juan may have brought to the Colorado much of the silt that appeared at Willow Beach during the three periods of turbid flow in 1935, but the evidence is not complete.

DISSOLVED MATTER

Changes in concentration of dissolved matter have been estimated approximately from the changes in sulfate, the principal acid radicle present in the Colorado River water. The determinations of sulfate have shown that a rapid increase in concentration of dissolved matter in the main river usually accompanies an increase in the quantity of suspended matter. The variations in sulfate at the Willow Beach Station, shown in Fig. 2(*a*), are of significance, therefore, in confirming the evidence afforded by the silt that, at times of silt discharge, water entering the reservoir is going through the reservoir without complete mixing. This evidence of absence of mixing is in agreement with the observations on the Rio Grande, where, it is reported by Fiock and Scofield[12] that the soluble salt content of the outflow increases materially during the periods of turbid flow. The simultaneous increases in sulfates and suspended matter at the Willow Beach Station would seem to indicate that they are definitely related to each other. The interval of about eight days between the increase at Grand Canyon and the increase at Willow Beach appears to be a reasonable time for water to flow the 275 miles from the Grand Canyon Station to the Willow Beach Station, including 70 to 90 miles through Lake Mead, with due allowance for the velocity of flow through the lake, resulting from an average slope of 3 or 4 ft to the mile of the bed of the reservoir, on which the turbid water probably flows beneath the quiescent clear water.

SPECIFIC GRAVITY

Simple experiments can be made in the laboratory to show that water of greater specific gravity, whether such specific gravity is obtained by decrease in temperature, the solution of soluble material, or the suspension of solid material of such fineness that it will stay in suspension for several hours, will find its way to the bottom of a dish containing water of less specific gravity. If there is any flow of water through the dish, the water of greater specific gravity will move along the bottom to the outlet.

Causes for the differences in specific gravity should be considered on the assumption that the relatively rapid flow of unmixed water through a long reservoir is due to: Differences in specific gravity; the slopes of the surfaces of water of greater specific gravity; or the slope of the sediment on which the flow takes place. In the studies reported in "Hydraulic Laboratory Practice,"[3] the phenomena were discussed wholly on the basis of differences in temperature, although the differences in specific gravity of the water used in the laboratory experiments appear to have been obtained generally by adding a solution of salt and not by changing the temperature. As a result of those studies it was concluded that water of greater specific gravity due to lower temperature might flow essentially unmixed through a basin or reservoir containing water of less specific gravity, and that the depth at which the flow would take place would be determined by the specific gravity of the colder water. This same effect as related to temperature was discussed[13] by Armin Schoklitsch in 1922.

A new aspect, evidently not previously studied extensively and, perhaps, not pertinent in the foregoing studies,[3] is presented in connection with the Colorado River and doubtless many other silt-laden streams, by a water made heavy because of a load of fine silt that is not quickly dropped even when the velocity is reduced to zero. This fine silt is associated so closely with the water by which it is carried that it apparently increases the specific gravity of the water. The range in specific gravity due to the presence of fine silt may be much greater than that due to differences in temperature. Under some conditions, therefore, water of an inflowing stream, even if it is higher in temperature, may not remain on the surface of a reservoir but may sink to the level determined by its greater specific gravity due to its load of fine silt. Mr. Fiock[8] has stated that the temperature of the outflow from the Elephant Butte Reservoir during periods when turbid water is passing through the reservoir, not on its surface, is about 6° higher than the temperature of the reservoir water. When the outflowing water becomes clear, its temperature drops to that of the reservoir water. Unfortunately, there are no records of the temperature of Colorado River water as it enters into, or flows from, Lake Mead; nor of the water in Lake Mead at various depths. No attempt has yet been made to find the depth of the flow of unmixed turbid water through Lake Mead, but it is tentatively assumed that the flow of turbid water is just on top of previously deposited silt and that it follows the original channel of the river.

---

[12] *Transactions*, Geophysical Union, 1934, Pt. 2, p. 472; also "The Movement of Silt through the Elephant Butte Reservoir", by C. S. Scofield. (Unpublished memorandum, February 17, 1936).

[13] "Einfluss der Durchleitung von Flusswasser durch Seen auf deren temperatur", Sonderheft to *Wasserkraft*, 17, 1922.

The differences between the specific gravity of the incoming water and of the lake water may be greater than the difference in specific gravity caused by differences in temperature. The specific gravity of pure water is 0.993 at 100° F, and has a maximum of 1.000 at 39.2° F. The specific gravity of the water that flowed through Lake Mead in October, 1935, ranged from 0.995 to 1.008, showing a greater variation than could be caused by the most extreme natural differences in temperature. Approximate values for the specific gravity of the turbid water that passed Lake Mead and the percentages of suspended matter in the water as determined on samples collected at the Willow Beach Gaging Station are given in Table 2.

TABLE 2.—SPECIFIC GRAVITY AND PERCENTAGE OF SUSPENDED MATTER IN WATER OF COLORADO RIVER AT WILLOW BEACH GAGING STATION, OCTOBER, 1935

Date (1)	Specific gravity* (2)	Suspended matter (percentage by weight) (3)	Date (1)	Specific gravity* (2)	Suspended matter (percentage by weight) (3)
October 5	0.995	0.004	October 10	1.008	1.76
October 6	1.005	1.38	October 11	1.007	1.76
October 7	1.002	1.32	October 12	1.004	1.14
October 8	1.004	1.40	October 13	0.999	0.38
October 9	1.003	1.00	October 14	0.996	0.01

* Determinations made at 84.2° F, referred to pure water at 39.2° F.

On the basis of present information it appears, therefore, that the phenomenon of flow of essentially unmixed turbid water through a long reservoir at one season or another is not uncommon, and that it may be affected by temperature, dissolved salts, size of particles of silt, and the degree of coagulation of dispersion of the silt particles.

The observations herein recorded relating to the flow of turbid water from Lake Mead during 1935 may have peculiar value, because they have been made systematically throughout the period when stored water was discharged through tunnels at, or near, the base of the dam, and, therefore, was drawn from the bottom of the lake. Early in 1936, while water was still being discharged through these tunnels, some of the water passing the dam was drawn through the intake towers from a level about 250 ft above the base of the dam. Under these conditions on April 22, 1936, the river at Willow Beach became turbid shortly after noon, the silt appearing in the main current at first and in 10 min the entire section was filled with turbid water. At this time, the discharge below the dam was about 10 000 cu ft per sec, of which about 5 000 cu ft per sec came through the diversion tunnel and about 5 000 cu ft per sec came through the outlet works. In this period of turbid flow about 2 400 000 tons of silt was carried past Willow Beach. The gate in the tunnel was closed on May 1, and the river at Willow Beach became clear on May 2.

CONCLUSIONS

The passage of silt in considerable quantities through a reservoir may have much more than scientific interest and importance. One of the great unsolved problems pertaining to the detention of water in reservoirs relates to the gradual loss of capacity caused by the deposition of silt. If any considerable quantity of silt can be carried through the reservoir its effective life will be correspondingly increased. In the three periods in 1935 of turbid flow from Lake Mead described herein 6 000 000 tons, or about 2.5% of the estimated average annual load of silt brought to the lake, has passed through it. The quantity of silt carried through other reservoirs on rivers having different silt and run-off characteristics has not been recorded and, perhaps, may reasonably be assumed to be smaller than that carried through Lake Mead. However, the quantity of silt thus carried may well be of sufficient importance to warrant further consideration.

The question may naturally be raised as to the possibility of increasing the discharge of silt from reservoirs created by future dams by modifying the positions of and approaches to the discharge openings or the manner of their operation. It is suggested that a study of the conditions pertaining to the flow of silt through a reservoir may be worth while. Engineers who make future designs will surely want to know the conditions that make such passage of turbid water possible, in order that full consideration may be given to any advantages that may be practicable of attainment by modifications in the details of design of the dams or in the plans for operation.

The record of silt flow described herein may be important not only to engineers in their evaluation of silt problems related to many other reservoirs built, or to be built, on silt-laden streams, but also in connection with certain geologic and engineering studies related to the deposition of silt and possibly to the origin of subaqueous channels. It is hoped that there may be brought into the discussion other definite information related to the little understood phenomena associated with the flow of water through reservoirs, and to the possible applications of the phenomena that may have practical significance with respect to engineering problems.

DISCUSSION

O. A. Faris,[14] M. Am. Soc. C. E. (by letter).—Turbid water showing in the discharge from large reservoirs, in the opinion of the writer, is the result of disturbance of silt which was virtually in place; that is, it was no longer in suspension, but had settled to the reservoir bottom soon after entering the slack-water and formed a "flocculent" or "honeycomb" structure of a consistency, ranging from thick cream to heavy molasses. It flows readily on the slope of the reservoir bottom, by virtue of a greater specific gravity than water, and, finally, reaches the dam.

Water is discharged from Lake Kemp, a reservoir on Wichita River, near Wichita Falls, Tex., through a battery of concrete pipes with inverts at or below the elevation of the river bed. The control gates are about midway the length of the conduits, allowing the up-stream half of the pipes to be exposed to pressure at all times. There is evidence that the liquid mud flows from the place of deposition in the old river channel, and down the channel within the reservoir until blocked by the closed outlet gates. On opening the gates, the first rush of water carries a heavy load of silt, but after discharging all mud within easy reach of the conduits, the discharge becomes clear. Water from this reservoir flows down the river channel several miles where it is diverted into the main canal of the irrigation system.[15]

The general arrangement which provides for the outlet at or below the elevation of the bottom of the stream channel and the diversion of water to canals at some distance down stream from the storage dam is favorable for the discharge of deposited silt of the aforementioned character. In most of the Texas reservoirs the highest elevations of the bottom, in a cross-section, are on the immediate banks of the old stream channel; therefore, none of the silt that is deposited on the wide flat areas between the elevated ridge near the channel and the toe of the slope from the upland, can flow into the old channel and ultimately reach the outlet structure. It is believed to be advantageous to clear reservoir sites of brush, trees, and stumps, and to construct channels with a view to conveying the liquid mud, resulting from the deposition of suspended silt, into the old stream channel and thence through the outlet gates.

As further evidence that deposited silt, in the form of liquid mud, flows down the slopes on reservoir bottoms, attention is called to conditions in Medina Reservoir, near San Antonio, Tex. In September, 1930, this reservoir was empty. A careful inspection revealed that the hummocks on the large flat areas in the reservoir bottom were void of silt deposit although they had been submerged by water to depths ranging from 40 to 100 ft. for long periods of time. On the other hand, all depressed areas on the flats contained silt with maximum depths in the lowest places and tapering to zero depth up the slopes.

[15] "The Silt Load of Texas Streams", by Orville A. Faris, M. Am. Soc. C. E., *Technical Bulletin 382*, U. S. Dept. of Agriculture, 1933, pp. 37–39.

The dry material per cubic foot of deposit of "flocculent" and "honeycomb" structure, taken from the bottom of Lake Worth, near Fort Worth, Tex., and composed largely of colloidal sizes, contained 18.7 lb. of oven-dry material per cu ft of deposit. On the basis of 2.65 for the specific gravity of the dry material, water occupied 88.59% of the space and the absolute voids amounted to 88.66 per cent. A sample from the bottom of Lake Kemp, consisting of sizes crresponding to clay particles, contained 37.05 lb of oven-dry material per cu ft of deposit. On the basis of 2.658 for the specific gravity of the dry material, the space occupied by water was 76.76% and the absolute voids amounted to 77.63 per cent.

The water capacity, by volume of undisturbed soils, below the water-table, ranges from 31.3% for very fine sand to 49% for marly loam. Comparing the water capacity of marly loam with that of the sample silt deposit which contained about 89% water, by volume, it is seen that the latter has a greater capacity by 40%, than the former. This greater capacity is due to the difference in structure of the mass of soft silt deposited, from suspension, under water and remaining submerged.

The excess water held in the silt deposit by virtue of structure is liberated so slowly upon exposure of the deposit to the sun and atmosphere that it is practically all dissipated by evaporation and is not available as storage water.

The unconsolidated character of material deposited from suspension, under water and remaining below the water-table, will continue indefinitely. This is evident from the soft character of low-lying material in peat marshes. This soft material was deposited ages ago and still retains the "honeycomb" structure on account of its position below the water-table.

The release of the excess water can be accomplished only at the surface of the deposit, therefore, in large reservoirs, consolidation of such deposits can not occur until the stored water is drawn down exposing the soft material to the action of the sun and atmosphere.

PAUL A. JONES,[16] M. AM. SOC. C. E. (by letter).—The studies regarding transportation of silt through large reservoirs will, no doubt, be of great interest to engineers, and it is hoped that the work begun by the authors may be continued. However, it is the writer's opinion that studies made concerning the turbidity of water passing Boulder Dam in 1935, or even until the lake has been completely filled, should not be given much weight in connection with transportation of silt in the future.

There were certain topographic conditions that, no doubt, greatly affected the turbidity of the flow at Boulder Dam, especially during 1935. The canyon above the dam, in general, is in the shape of an arc, with the inside of the arc on the side of diversion through Tunnel No. 1, on the Nevada side. It is reasonable to assume that currents of water act similarly to currents of air, and will move toward the inside of the curve instead of following the original channel. Cold or heavy air will follow the inside of a curve, or the shortest distance, as may be observed in a tunnel constructed on a curve. It would seem fair to expect the greatest number of contraction cracks in the concrete lining of a tunnel on the outside of the curve, but the reverse is true, as the cold air in a draft follows the inside of the curve.

---

[16] Constr. Engr., U. S. Bureau of Reclamation, Glendive, Mont.

At Elevation 720 at Boulder Dam, which is about 30 ft above the top or back of Tunnel No. 1, the contractor constructed a railroad grade down the canyon on the Nevada side, principally from tunnel muck which was of a reddish brown color. Below this grade, on the same side of the canyon, at about Elevation 650, was a comparatively large sand-bar. Just above the entrance to the canyon, and also on the inside of the arc, blow-sand drifts extended in general to approximately Elevation 800. About three miles above the entrance to the canyon, there are at present (1937), or there will be, two rock islands which were connected by a blow-sand ridge, and the original current flowed east of the island farthest east.

If a check is made of the dates of turbidity of flow through the dam and lake-level elevations, it will be found that the first turbidity occurred soon after the sand-bar was well covered; the second turbidity occurred soon after the railroad grade was well covered, and was much redder in color than the usual Colorado River water; and that, a turbidity occurred soon after the ridge between the two rock islands was well covered, and at about the time that a change in current from the east side of the small island to the west side, would be expected. At the level of diversion through the towers, the canyon has little blow-sand or silt, and it is not likely that turbidity below the dam will again occur to the extent observed in 1935.

This discussion is not written to contradict any of the statements made in the paper, but as a possible explanation for the amount of turbidity in 1935 when the reservoir was being filled for the first time, and the current was being changed gradually to new and unstable ground, due to the fact that the canyon immediately above the dam takes the form of an arc, with the inside of the arc on the side of diversion, or the Nevada side.

It is well understood that river water carries large quantities of collodial silt in suspension, and studies relative to this material, no doubt, would be of great benefit to the Engineering Profession. For example, there is a shoal in San Francisco Bay, just west of Mare Island, which is composed entirely of colloidal silt deposited where the fresh waters of the rivers come in contact with a certain percentage of saline water from the ocean. Since the effect of tides is noted as far up the Sacramento River as the City of Sacramento, and the collodial silt is not deposited until it reaches a point nearly 100 hundred miles distant, and is there precipitated by salt, it is reasonable to expect that a large quantity of fine silt will be transported through Lake Mead.

Carl S. Scofield,[17] Esq. (by letter).—Hydraulic engineers are fortunate in having made available in precise form the information concerning a phenomenon that has been reported hitherto only in general terms.

---

[17] Agriculturist in Chg., Div. of Western Irrig. Agriculture, Bureau of Plant Industry, U. S. Dept. of Agriculture, Washington, D. C.

Observations that different waters may move together in the same stream channel with little blending, and that water may flow into, or through, a reservoir with little or no mixing, have been reported before but only circumstantially. The findings reported by Messrs. Grover and Howard, therefore, challenge attention and invite further inquiry. The reasons underlying the phenomenon described remain obscure.

The assumption that two different solutions brought together in the same container would automatically blend into one homogeneous mixture runs counter to daily experience. One naturally uses a spoon to stir a cup of coffee after the cream and sugar are added. In the case of reservoirs such mixing as occurs may be due in part to the effects of currents set in motion by inflowing water, by wind action on the surface, or in part to "inversions" caused by temperature changes that affect the specific gravity of the water. For example, if the surface water of a reservoir becomes colder than the deeper water, its specific gravity becomes higher and inversion occurs.

When turbid stream water enters a reservoir in the summer, if its temperature is higher and its salinity is lower than that of reservoir water, the normal behavior is for the silt to settle to the bottom and for the clear water to spread over the reservoir surface. On the other hand, if the inflowing turbid water is much more saline than the reservoir water the higher specific gravity due to salinity tends to offset the lower specific gravity due to temperature so that the water tends to stay with the silt and to move into the reservoir along the bottom.

Furthermore, the behavior of silt in relation to its transporting water appears to be influenced by the relative conditions of salinity. If the concentration of dissolved salts in the inflowing water is less than that of the reservoir water, flocculation and deposition of the silt appear to be hastened. If, conversely, the concentration of dissolved salts in the inflowing turbid water is higher than that of the reservoir water, the tendency is to retard the flocculation and deposition of the silt. The combined effect of silt and of dissolved salts on the specific gravity of water, of course, is much greater than the effect of temperatures, at least within the ranges that ordinarily occur in streams and reservoirs.

The foregoing are largely theoretical considerations. Engineers do not, as yet, have enough facts to explain convincingly why the incoming silt is sometimes deposited at the head of a reservoir and, at other times, is carried far along the bottom or even all the way through the reservoir. One phenomenon would probably be regarded as quite as "normal" as the other if one knew more of the facts and factors involved. Both are known to have occurred at Boulder Dam and at Elephant Butte Dam.

IVAN E. HOUK,[18] M. AM. SOC. C. E. (by letter).—The authors have contributed some valuable information regarding the character and quantity of suspended material carried through Mead Lake. The paper is especially noteworthy since outflow conditions at the reservoir during the period covered by the silt observations will never again be experienced. During 1935 lake water was released through one of the diversion tunnels at about the normal low-water surface of the Colorado River. About May 1, 1936, the tunnel flow was shut off; not only by closing the regulation gates, inside the tunnel, but also by permanently sealing the up-stream end of the tunnel with a 50 by 50-ft Stoney gate. Since that time water has been released through cylinder gates in the intake towers. These gates are located at heights of approximately 250 and 400 ft above the tunnel gates. They will be used in all future regulation of reservoir outflow for irrigation and power purposes.

---

[18] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

Unfortunately, no measurements of river water temperature were made at the up-stream end of Mead Lake during 1935. However, temperatures of river water at the dam site have been observed since April, 1930. These measurements were being made, daily, during the period covered by the authors' silt observations. After storage began on February 1, 1935, the temperature measurements were made in the reservoir outflow. Fig. 3 shows the results of the observations; also the daily air temperatures, mean monthly air temperatures, and mean monthly water temperatures.

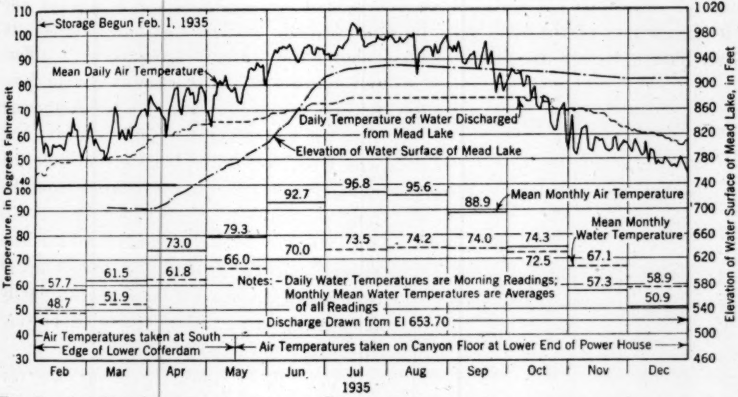

FIG. 3.—AIR TEMPERATURES AT BOULDER DAM COMPARED WITH TEMPERATURES OF WATER DISCHARGED FROM LAKE MEAD DURING PERIOD FROM FEBRUARY 1 TO DECEMBER 31, 1935.

A comparison of the daily water temperatures during 1935 with those measured during previous years shows that the reservoir inflow temperatures must have been approximately the same as, or slightly lower than, the lake temperatures at the elevation of the tunnel gates, during the periods of silt movement through the reservoir. Consequently, the inflow densities must have been approximately the same as, or slightly greater than, the lake densities at the tunnel level; and the silty inflow undoubtedly followed the original river channel along the lake bottom to the open gates as assumed by the authors. Since the gates were closed silty inflow probably has moved along the lake bottom to the level of its density, then spread out, and gradually come to rest at that level. The fine silt particles, which might have been discharged with the outflow had the tunnel gates remained open, are now settling to the lake bed and are gradually becoming consolidated under the lake pressures.

Measurements of water temperature at different depths in Mead Lake were begun in June, 1936, and are being continued at monthly intervals. The securing of samples of the lake water at different depths, for chemical and silt analyses, is now (1937) being considered. When such data become available, it should be possible to discuss the movement of turbid water through the reservoir much more adequately. The writer believes that, some time in the future, silty flood water, having the same density as the lake water at the elevation of the cylinder gates, may enter the reservoir, flow through the lake at the level of its density, and be noticeable in the reservoir discharge.

The conditions under which turbid water may flow through a reservoir instead of along the bottom, or instead of being rapidly diffused at the up-stream end of the lake, may be discussed on the basis of the temperature distribution within the lake. Fig. 4 shows the water temperature at different elevations in Elephant Butte Reservoir on June 18, 1934. Assuming that the water had the same salinity and was free from silt at all elevations, the density curve can be calculated from the temperature curve. Such a curve will show approximately constant densities from the bottom of the reservoir up to about Elevation 4 270, then gradually decreasing densities as the temperature increases toward the surface.

FIG. 4.—TEMPERATURE DISTRIBUTION IN ELEPHANT BUTTE RESERVOIR ON JUNE 18, 1934.

Silty flood flows, entering the reservoir with a density greater than the water at the lake bed, would be expected to flow along the original river channel beneath the body of the lake. Similar flows, entering the reservoir with a density the same as the lake water below Elevation 4 270, would be expected to spread out laterally and vertically through the entire reservoir section below that elevation. However, silty floods entering the reservoir with a density equal to the lake water at some elevation above 4 270, as, for instance, at Elevation 4 300, would be expected to spread out laterally at that level and to flow through the reservoir at approximately that elevation without diffusing through appreciable vertical distances, just as the water did in the laboratory experiments described by Mr. Freeman, and cited by the authors.[3] In any case, the appearance of silt in the reservoir outflow is probably dependent upon the continuance of a relatively large silty inflow at the upper end of the reservoir until the silty flow has had time to reach the outlet gates.

Temperature measurements in existing reservoirs show that during some periods of the year, usually during the winter months, lake densities are approximately constant through the entire vertical section. At such times flood flows, entering the reservoir with a density the same as the reservoir water, would be expected to diffuse laterally and vertically through the entire cross-section of the reservoir. Consequently, under such conditions, only exceptionally large and long-continued inflows would cause movement of the turbid water to the outlet gates.

The writer doubts whether it will ever be desirable to design irrigation reservoir outlets so as to secure a maximum outflow of turbid water. As mentioned by Mr. Fiock, in the reference cited by the authors,[a] the silt discharged at such times would be deposited in the canals, or carried through the canal systems, and deposited on the farm lands, either of which would be objectionable. However, investigation of the problem is well worth while from the scientific standpoint, even though the studies may produce no results of great economic value. The authors have rendered a service to the Engineering Profession in bringing the matter up for discussion.

William P. Creager,[19] M. Am. Soc. C. E. (by letter).—The contents of this paper are of exceedingly great interest. It is hoped that more data of like character will be forthcoming for other cases.

When water containing silt in suspension enters a relatively clear reservoir, the chances of its passage through such reservoir essentially unmixed, depend upon: (1) The volume of the incoming water; (2) the slope of the bed of the reservoir; (3) the roughness of the bed of the reservoir; (4) the length of the reservoir; (5) the specific gravity of the incoming water; and (6) the size of the particles in suspension.

For the same specific gravity, the greater the volume of inflow the deeper will be the stream of unmixed water; and this factor, together with the slope and roughness, affects its velocity of flow just as in an ordinary stream. It is obvious that the greater distance the unmixed stream has to travel, the greater will be the opportunity for the suspended matter to settle.

All these conditions must be taken into consideration for a particular problem and additional information similar to that furnished by the authors will provide the basis of the constants of flow.

The specific gravity of the incoming water depends upon: (*a*) Its temperature; (*b*) its dissolved matter; and (*c*) its suspended load. The temperature of the water entering the lake may be greater than that of the lake with a resulting tendency to keep on the surface. However, the authors have shown that, for this case, the variation in specific gravity due to temperature is negligible in comparison with the variation due to suspended load.

---

[19] Cons. Engr., Buffalo, N. Y.

Although the quantity of dissolved material undoubtedly affects the specific gravity of the incoming water, there is no evidence in Fig. 2 to show that it had much influence on the discharge of silt from Lake Mead, as indicated by the following notes: (1) There was no increase in dissolved matter prior to the April discharge of silt; and (2) dissolved matter has no chance to settle, as does suspended matter. Therefore, one would expect that, if the greater specific gravity of the water due to dissolved matter were predominant, there would be some similarity between the inflow and outflow of dissolved matter. However, in August, the outflow was reduced while the inflow was increasing; whereas, in November, the reverse is true.

The writer wishes to discuss the suspended load, first, on the basis of size of particles; second, on the basis of total volume in suspension; and, finally, on the basis of the percentage of material in suspension.

Small particles settle in water more slowly than large ones. Therefore, other conditions being the same, it would be expected that turbulence caused by fine particles would find its way through the lake more readily than that caused by large particles. However, the quantity of fine particles does not seem to be the predominating feature at Lake Mead, for the following reason: The variation in size of particles entering the lake is shown in Fig. 2(*b*) of the paper. The authors state that "whenever there was an increase in load of suspended matter at the Willow Beach Station there had been a prior increase in the quantity of material less than 20 microns in diameter at Grand Canyon." However, the reverse of this statement is not the case. For instance, a considerable discharge of suspended matter from the lake occurred after the April increase in quantities of material less than 20 microns, but in June there was a still greater increase in fine particles with no resulting discharge of suspended matter from the lake. This same argument may be applied to show also that neither the total quantity of suspended matter entering the lake nor the total flow is the predominating feature affecting discharge of suspended matter from the lake.

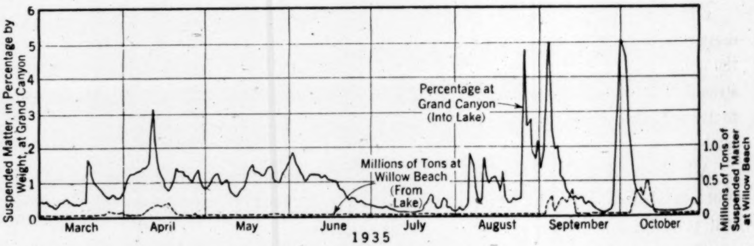

FIG. 5.—SUSPENDED MATTER, PERCENTAGE BY WEIGHT, INTO THE LAKE AND TONS OUT OF THE LAKE.

The authors state that "there will naturally be speculation as to the reason why the high water of May and June, with its heavy silt load at

Grand Canyon, did not produce a turbid discharge from Lake Mead." The writer believes that the answer is to be found in his Fig. 5, in which the percentage of suspended matter entering the lake (taken from Table 1) and the tons of suspended matter discharged from the lake (taken from Fig. 2(*c*)) are plotted. It will be noticed that there is a distinct agreement between these plottings. There was always a discharge of silt from the lake when the percentage of suspended matter entering it was greater than about 2 and no discharge of silt from the lake when the percentage was less than 2. The authors' speculation will be answered when it is noticed that the higher water of May and June with its "heavy silt load" by volume actually had a relatively small percentage of silt, and therefore, a relatively low specific gravity.

The fact that, in March, silt was carried through with only 1.7% of suspended matter whereas, in June, it did not carry through with 1.9%, may be accounted for by the fact that, in March, the percentage of dissolved matter was greater and the temperature probably less, resulting in greater specific gravity for the same percentage of suspended material.

It is not possible, with the data available, to form final conclusions; but the facts presented in the paper indicate that:

1.—It requires a certain specific gravity of the incoming water to carry the silt through the lake.

2.—At Lake Mead, the predominating feature affecting specific gravity was the percentage of total suspended load, although the percentage of fine particles and dissolved matter and the temperature may have had a minor influence.

3.—For the physical conditions at Lake Mead, it requires a specific gravity corresponding at least to that for about 2% of total suspended matter.

Harold K. Palmer,[20] M. Am. Soc. C. E. (by letter).—An unexpected phenomenon of scientific interest is described in this paper. Although it might be that the useful life of this large project would be increased slightly by proper operation, as the authors suggest, any possible increase in life would be small because the percentage of silt fine enough to be carried through such a long reservoir would be small. The coincidence of the increase in specific gravity of the water at Willow Beach observed from October 5 to 14, 1935, with the period of turbidity, suggests that this increased specific gravity is probably the explanation of the passage of turbid water through the lake. The authors show that the increased specific gravity is almost entirely due to the concentration of fine material, and Figs. 2 (*b*) and 2 (*c*) show that periods of turbidity follow sharp peaks of fine material observed at Grand Canyon. Therefore, a solution should be sought in the behavior of two bodies of water of different specific gravity when brought into contact with each other.

[20] Chf. Draftsman, Los Angeles County Sanitation Dists., Los Angeles, Calif.

In collaboration with A. M. Rawn, M. Am. Soc. C. E., the writer made an extensive series of experiments on the mixture of fresh water and sea water.[21] This investigation dealt with the behavior of a lighter water introduced at the bottom of the body of heavy water which is the opposite of the conditions encountered in Lake Mead, but some of the results can be easily applied to both cases.

In the experiments with sea water it was found that the mixture of the two waters occurred in two stages, the first being a violent mixture caused by the turbulence along the plane of contact as the fresh water rose rapidly to the surface of the salt water, followed by the second stage when the somewhat diluted fresh water spread over the surface of the salt water. The term, "initial dilution", was used to express the degree of mixing that had been affected at the end of the first stage, when the water reached the surface. All the experiments revealed the fact that if this initial dilution was small (about nine parts of salt water to one part of fresh), the final mixing was very slow and the field would spread to large dimensions before disappearing at a theoretical dilution ratio of 225 to 1. It was also found that if the natural spreading of the field was interfered with in any way, such as being confined by a sea wall, further dilution was much slower and the fresh water tended to travel without much further mixing.

The authors show that about eight days after the specific gravity of the water at Grand Canyon showed an increase from 0.995 to from 1.005 to 1.008, the turbid water appeared at Willow Beach. The specific gravity of sea water is 1.026. Reducing this figure to 1.016 would be equivalent to the change in specific gravity noted at Grand Canyon and would be accomplished by a dilution of approximately two parts of salt water with one of fresh. Such a mixture would be quite stable and could be expected to continue its travel for a long distance without great dilution.
